P. J. SMAIL, T. E. ISLES, AND R. S. ACKROYD

Departments of Child Health and Biochemical Medicine, Ninewells Hospital and Medical School, Dundee

SUMMARY A case of long-standing mild hypothyroidism is described. This was caused by partial TSH deficiency probably of hypothalamic origin, with no other pituitary hormone deficiencies, although with a decreased response of FSH and LH to LHRH.

Low thyroid-stimulating hormone (TSH) hypothyroidism of hypothalamic or pituitary origin is usually accompanied by other pituitary hormone deficiencies (Kaplan, 1975), isolated TSH deficiency in childhood having been described in only one report since the advent of modern TSH assays (Miyai *et al.*, 1971). We report a case of low-TSH hypothyroidism in a child without evidence of other pituitary deficiencies although with decreased response of luteinising hormone (LH) and follicle-stimulating hormone (FSH) to luteinising hormone-releasing hormone (LHRH).

Case report

A 6-year-old boy was admitted with a febrile illness. He was noted to have a deep voice, a protuberant abdomen, and an exaggerated lumbar lordosis. His height was on the 25th centile. He had not developed his first tooth until age 13 months and was said always to have been intolerant of cold. Serum thyroxine (T4) was 42 nmol/l (3·2 μg/100 ml). Our laboratory mean is 110 nmol/l (8·5 μg/100 ml) and range ± 2 SD 75–145 nmol/l (5·8–11·2 mg/100 ml).

Other thyroid function studies included serum triiodothyronine (T3) 2·1 nmol/l (1·37 μg/100 ml), T3 index 109%, free T4 index 39, and TSH<0·6 mU/l. Antithyroid-cytoplasmic antibody (by fluorescent antibody technique) and antithyroglobulin antibody (by tanned red cell test) were negative. A ^{99}technetium scan showed a normally placed thyroid gland. The responses of serum TSH, T4, T3, T3 index, and free T4 index to an IV dose of 200 μg thyrotrophin-releasing hormone (TRH) are shown in the Table. Serum TSH increased to a maximum of 5·2 mU/l at 20 minutes. Bone age was 3·3 years at a chronological age of 6·3 years (Tanner Whitehouse) and skull *x*-ray was normal. *X*-ray of the hips showed advanced changes of Perthes's disease bilaterally. His intelligence was within the normal range although he was having coaching at school for reading and arithmetic.

After 0·25 mg tetracosactrin IM, serum cortisol rose from 343 nmol/l (12·3 μg/100 ml) to 723

Table *Response to an intravenous dose of 200 μg thyrotrophin-releasing hormone*

	Time (min)				*Laboratory*	
	0	*20*	*60*	*180*	*Mean*	*Range ± 2 SD*
TSH (mU/l)	3·5	5·0	2·4	1·7	—	0–5
T4 (nmol/l)	58	69	47	56	110	75–145
T3 (nmol/l)	2·0	2·1	2·1	2·2	1·7	1·0–2·4
T3 uptake %	106	109	104	105	105	97–113
Free T4 index	55	63	45	53	103	70–135

Conversion: SI to traditional units—thyroxine: 1 nmol ≈ 0·077 μg/100 ml, triiodothyronine: 1 nmol/l ≈ 0·65 μg/100 ml.

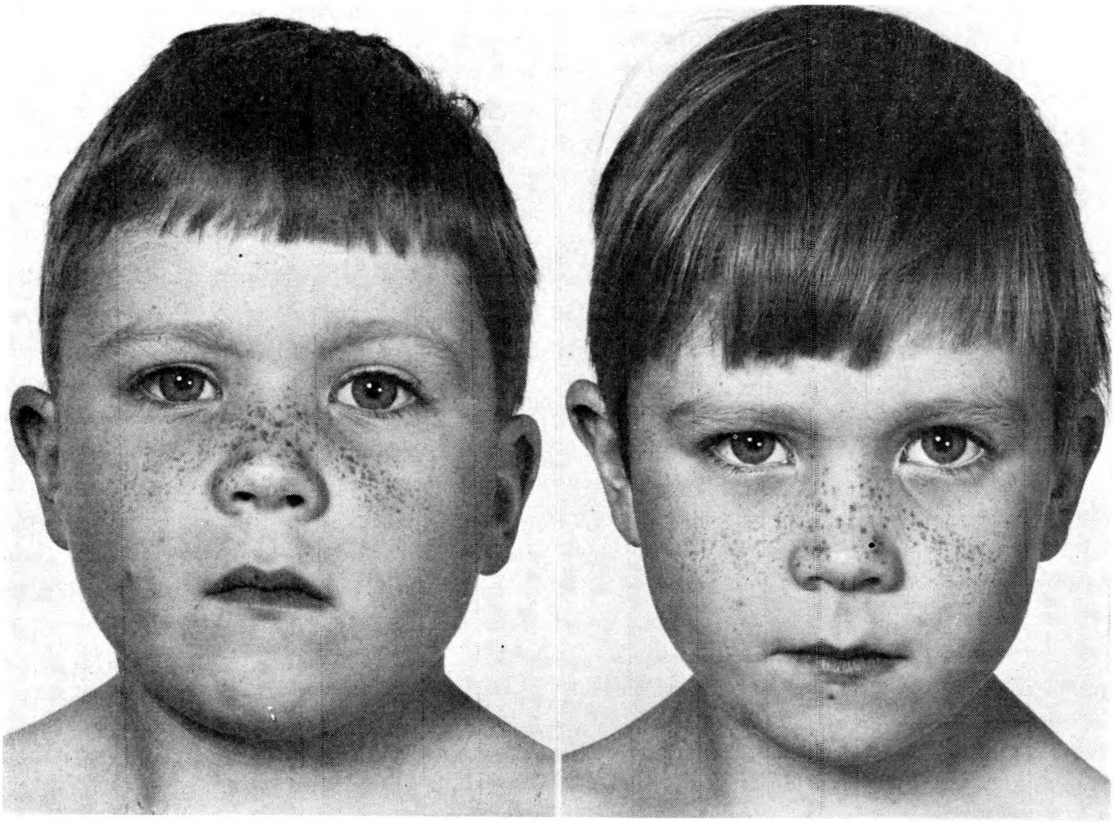

Figure *The patient before and 6 months after treatment with thyroxine.*

nmol/l (26·0 μg/100 ml) at 30 minutes. Basal serum LH was 1·5 U/l and basal FSH 0·9 U/l with no significant rise of either after an IV dose of 100 μg LHRH. Basal serum testosterone was 3120 nmol/l (0·9 ng/ml), basal serum prolactin 260 mU/l, and the maximum serum growth hormone (GH) response in an insulin tolerance test producing adequate hypoglycaemia was 9·6 mU/l, and the maximum serum cortisol 46·7 μg/100 ml (1298 nmol/l). A stimulated GH level of 16 mU/l is regarded by our laboratory as excluding significant deficiency. An exercise test GH level after treatment with thyroxine was 18·7 mU/l, showing that the previous poor stimulation by hypoglycaemia was due to thyroxine deficiency and not to lack of GH. Treatment was begun with oral L-thyroxine increasing to 0·2 mg daily with a resultant rapid change in body habitus and general increase in level of activity (Figure). The height velocity during the first year of treatment was 7·6 cm (equivalent to the 97th centile) and his achievement at school improved considerably with capabilities now described as well above average; special teaching was no longer required. The TRH stimulation test was repeated after one year of treatment (thyroxine being withheld for 8 weeks before the test) as it has been suggested (Boehm *et al.*, 1976) that an improvement in TSH response may occur in isolated TSH deficiency after treatment with thyroxine. Serum TSH rose from a basal level of 2·2 mU/l to a maximum of 4·3 mU/l at 20 minutes, serum prolactin rising from 165 to 750 mU/l. Bone age was 4·4 years at a chronological age of 7·7 years, an advance of 1·1 after 12 months' treatment.

Discussion

We interpret the results in this patient as indicating partial TSH deficiency, possibly of hypothalamic origin, without other clinical evidence of pituitary hormone deficiencies. The response of TSH during the TRH test suggests the presence of some active TSH, while the levels of serum T3 and free T4 index do not suggest either an abnormality of thyroxine protein binding or a defect of peripheral thyroxine metabolism. It is difficult to interpret the significance of the decreased response of LH and FSH to LHRH in a child of this age. The two sisters reported by Miyai *et al.* (1971) were said at the age of 12 and 14 years respectively to have early breast development and detectable urinary LH and FSH. Our patient seems similar to Case 23 of Chaussain *et al.* (1974) who had TSH deficiency with a normal response to TRH but no significant rise of LH and FSH with LHRH.

That this sort of case and other cases of congenital secondary hypothyroidism may be missed, is an objection to the use of TSH rather than T4 as the primary test in screening for neonatal hypothyroidism. However, although this patient has a history of hypothyroidism dating back to neonatal life or at least to early infancy, the hypothyroidism was of mild degree with no deficit in intelligence.

We thank Dr Valerie Marrian for referring this case to the endocrine clinic in Dundee, Miss Margaret Browning and Dr Elizabeth Hunter for endocrine assays, and Dr Constance Forsyth for advice.

Ring 20 chromosome in a child with seizures, minor anomalies, and retardation

JANET M. STEWART, NICHOLAS CAVANAGH, AND DAVID T. HUGHES

Institute of Child Health, and The Hospital for Sick Children, London

SUMMARY A patient is reported with seizures, developmental delay, and minor physical anomalies. Karyotype showed a ring formation of chromosome number 20. Previously reported patients with this chromosomal aberration have typically had seizures and behavioural disorders with considerable variation in the degree of physical abnormality and mental retardation. A correct diagnosis in such a case is important for accurate genetic counselling.

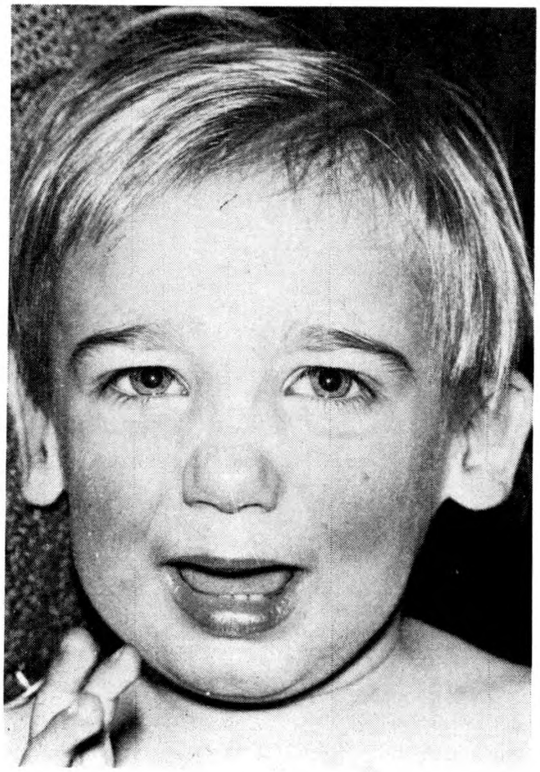
Many new chromosomal syndromes have been reported since the introduction of banding. Most of these are associated with dysmorphic features, multiple anomalies, and mental retardation. A ring formation of chromosome 20, on the other hand, has been reported in patients with negligible physical anomalies, severe seizures, and variable retardation (Table). We report an additional case to emphasise that seizures with slight dysmorphism may be a manifestation of a chromosomal abnormality.

Case report

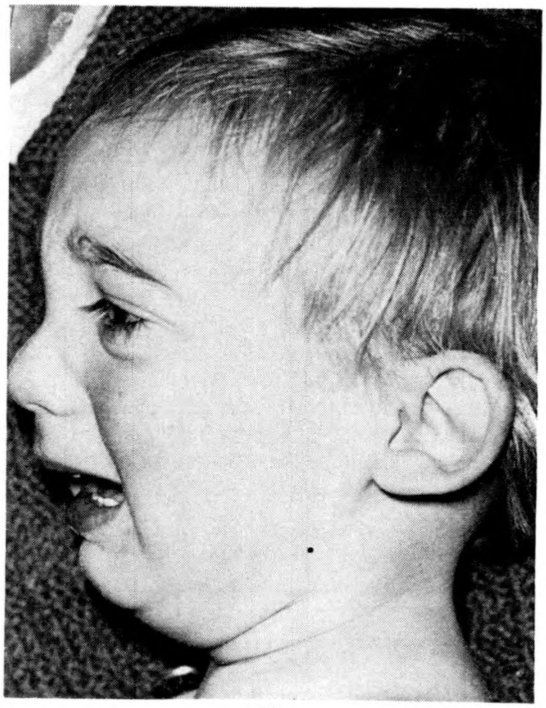
Case 1 was the product of an uncomplicated, term pregnancy and weighed 2800 g at birth. He was a slow feeder initially. He smiled at 7 weeks, sat unsupported at 10 months, crawled at 14 months, and pulled to stand at 20 months. He had no speech at 25 months. At 12 months he was noted to have episodes lasting 30 minutes in which his head turned to the left and his eyes were glazed. By 14 months he was having spells lasting 20 seconds with mouthing movements and twitching of the right arm and leg, followed by excitement. These occurred up to 5 times daily and continued when he was placed on phenobarbitone.

His mother was 36 and his father 39 at the time of his birth. His mother had a nodular goitre. She had had one miscarriage before the patient's birth and has had one subsequently. She has a brother with a cleft lip and palate and an uncle with well-controlled epilepsy. There was no consanguinity.

When examined at 16 months, his weight was at the 10th centile, height at the 25th, and head circumference between the 10th and 25th (46·5 cm) (Fig. 1). Although his face was not strikingly unusual, he did not resemble either parent. He had a sloping forehead, synophrys, long eye lashes, and no epicanthic folds. The nose was small and flattened and he had a long philtrum. The palate was



(*a*)



(*b*)

Fig. 1 *Facial appearance of patient,* (*a*) *full face and* (*b*) *profile.*

moderately high arched and there was micrognathia. The ears were posteriorly rotated and prominent with a poorly developed antihelix. Both testes were descended and he had a glandular hypospadias. He had scattered eczematous patches. There was a groove between the first and second toes, but palmar creases and dermatoglyphics were otherwise unremarkable. Neurological examination was normal except for mild hypotonia.

Routine blood studies including amino-acids, immunoglobulins, and a congenital infection screen were normal. Other normal studies were CAT, electroretinogram, and skull films. An electroencephalogram showed occasional paroxysmal features without clear lateralisation. On the Griffiths's developmental chart he functioned at the 12-month level. A G-banded karyotype showed 3 normal cells and 21 cells with a ring 20 chromosome (46, XY/46, XY20r Fig. 2). Both parents had normal karyotypes. At the parents' request fibroblast cultures were not done.

Discussion

A ring chromosome is formed by the partial deletion of both the long and short arms with rehealing in a ring formation. This is an unusual abnormality and often unstable.

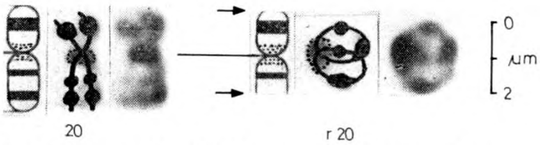


Fig. 2 *Giemsa-banded chromosomes showing, from left to right, drawing and photomicrograph of the normal and the ring chromosome no. 20* (*International Standard Diagram*).

Previous cases. Four other patients with a ring 20 chromosome have been reported (Table). Atkins *et al.* (1972) described a 7-year-old boy (Case 2) with the ring present in most of the cells. Behaviour problems began at one year and grand mal seizures at 6½. His physical examination was said to be normal and IQ was estimated at 50. Faed *et al.* (1972) reported an 11-year-old boy (Case 3) with a ring 20 in 60% of his cells. He too was said to be of normal appearance except for bilateral epicanthi and unusual dermatoglyphics. Temporal lobe seizures started at age 4. They were poorly controlled and associated with behavioural deterioration. His IQ

*Epicanthic folds only, †normal development until grade 6.

was 80. A 23-year-old woman (Case 4) was reported by Uchida and Lin (1972) with a ring 20 in 22% of her lymphocytes, the remaining cells being normal. She was said to have developed normally as a child although she was a 'crib rocker', a head banger, and had nightmares. 'Petit mal' began at age 10 years and grand mal seizures at age 12. Her developmental progress ceased at grade 6 (about 12 years). Her behaviour was erratic, impulsive, and juvenile. She had hyperreflexia and was clumsy in performing finer movements; no dysmorphic features were described. Her IQ was 62. Case 5 was found by Jacobs *et al.* (1978) when screening patients in an institution for the retarded. He had a ring 20 chromosome in all cells counted. He was said to have been normal until 18 months when he had a fall with seizure and fever (41·1°C). At age 27 years, he was profoundly retarded, had mild microcephaly, small testes, kyphoscoliosis, and flexion contractures, but as in the other cases, no dysmorphic features were described.

These patients have several features in common: all had seizures and 3 had behavioural abnormalities of various types (aggressive, immature, impulsive). Intelligence quotients varied from 18 (Case 5) to 80 (Case 3). Our patient also has seizures, developmental retardation, and only minor physical abnormalities. None with a confirmed ring 20 was dysmorphic. However, an infant (Case 6) reported by de Grouchy *et al.* (1972) had a ring formation of an unspecified F chromosome. This child had a dysmorphic face, severely retarded development, and seizures beginning at 3 months. He died at 7 months of age.

When a child presents with seizures, behaviour disturbance, developmental delay, and either no physical anomalies or minor ones, a karyotype may not be requested. Indeed these are common problems and are only rarely associated with a chromosomal abnormality, yet it is important to know when one does exist. The parents of such a child should receive genetic counselling and the recurrence risk will vary with the cause of the problem. The presence of a chromosomal abnormality in the child and normal karyotypes in both parents implies a low recurrence risk with the option of prenatal diagnosis. Mental retardation is variable in this and other chromosomal abnormalities and some of these individuals may reproduce. The recurrence risk in their children is then increased (even when the patient is a mosaic) and amniocentesis is clearly indicated.

The possibility of the chromosomal aberration being secondary to anticonvulsants was raised by Atkins. All the reported patients had seizures and were probably on medication. Acquired deletions of chromosome 20 have been described in various haematological disorders, such as polycythaemia vera (Millard *et al.*, 1968) and acute leukaemia (Kiossoglou *et al.*, 1965). The presence of the abnormality in 3 of 10 fibroblasts examined in Case 3 (Table), its restriction to chromosome 20, and the variety of drugs used make this explanation unlikely.

We thank Dr Edward Brett for allowing us to report his patient and for the many helpful suggestions made by him and by Professor Cedric Carter. We also thank Miss Doreen Farrington and Miss Janette Rae for their help in the cytogenetic laboratory.

Scottish Paediatric Society

At the Annual General Meeting held at the Royal Hospital for Sick Children, Glasgow, on Friday, 17 November 1978, Dr W. H. Galloway was elected President in succession to Dr R. A. Shanks. Dr E. N. Coleman was re-elected Secretary and Treasurer.

The third Jubilee Lecture entitled 'The purpose and philosophy of developmental assessment' was delivered by Professor R. S. Illingworth.

Scientific communications

Follow-up of low birthweight children at early school age. C. M. Drillien. University of Dundee.

88% of an initial sample of 299 infants of birthweights 2000 g and less were followed up to ages 6½–7 years and their progress at school examined. Children who had exhibited transient abnormal neurological signs in the 1st year of life had more problems at school than control children of similar birthweights who had been neurologically normal throughout. Low birthweight children who were considered to have suffered early intrauterine insult were more often excluded from normal school or were more often found to have problems therein than children whose low birthweight (premature delivery or normal dates) was attributed to other causes. Performance in school for survey and control children was correlated with socioeconomic class. For low birthweight children this was a more accurate predictor of later school performance than any other factor.

Radiation characteristics of phototherapy units. I. Smith (introduced), D. H. Wright (introduced), and A. J. Keay. Western General Hospital, Edinburgh.

Clinical studies of the effectiveness of phototherapy in this country seldom include precise measurements of radiation received. A study is in progress to measure the radiant energy output at different wavelengths from various types of phototherapy units using a Macam spectroradiometer. Once these units have been calibrated it is hoped to develop a badge type of radiation measurement (similar to that used in *x*-ray work) for the measurement of light radiation during treatment. The present study gives the measurements of spectral output from various units over both short and long periods, including assessment of the background radiation. First results show that the long-term stability of the units is good but that a considerable difference exists in the spectral characteristics of units from different manufacturers. Background radiation varies to a degree which causes up to a 50% increase in radiation on sunny days. These findings in relation to the clinical effectiveness of the phototherapy units are being studied so that optimal radiation characteristics for treatment by phototherapy can be established.

Faecal viruses and morbidity among babies in Glasgow. T. M. Scott, C. R. Madeley (introduced), B. P. Cosgrove (introduced), and J. P. Stanfield. Stobhill General Hospital, Glasgow.

During a monthly survey of growth and development of babies from birth to 18 months in two Glasgow housing estates, diarrhoea was found to be a common cause of morbidity in babies from the less salubrious area. Identification of faecal viruses in stool samples taken from these infants led to a more extensive survey. Weekly visits were paid to 27 infants in their homes so that details of illnesses could be recorded and stool samples collected for EM. Faecal virus excretion during hospital admissions was monitored by daily sampling if possible. The findings show that although virus excretion is common and is frequently recurrent, symptoms of illness are not inevitable. The pattern of excretion during hospital admissions is complicated by the multiplicity of virus types seen during a single admission, and the occurrence of hospital-acquired infection. Identification of enteropathogenic *Escherichia coli* and viruses in combination raises doubts about the validity of ascribing symptoms to any single agent.

Genetic component in febrile seizures. J. B. P. Stephenson. Royal Hospital for Sick Children, Glasgow.

It is generally recognised that there is a genetic basis to many febrile convulsions (FC). The usual explanation is that the convulsive threshold is lower in early childhood; by this it is meant that the *epileptic* convulsive threshold is lower. 630 children referred for EEGs after at least one FC and who also had ocular compression were studied, and the resulting cardiac asystole was measured. Prolonged cardiac asystole after this manoeuvre was found to be directly related to a family history of FC. Experimental 'anoxic seizures' after excessive oculocardiac reflex were also studied in approximately 100 children in whom it was found that the convulsive threshold—the *nonepileptic* convulsive threshold—was related to age, and was low at ages when genetic FC are common. The genetic basis for familial FC is an excessive sensitivity of the vagocardiac reflex at an age when the anoxic/ischaemic convulsive threshold is low. The details of this mechanism and its relation to cerebral pathology and to epilepsy, have yet to be elucidated.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onward all manuscripts submitted should accord with the new style.

Correspondence

Conservative care of the newborn baby

Sir,

We were disturbed to read Dr Hughes-Davies's report (*Archives*, 1979, **54**, 59) and should like to explain why we regard some of his conclusions as unjustified.

Dr Hughes-Davies describes his hospital care of 14 892 newborn infants delivered in Salisbury during 1969–76. In his management of small or ill babies he places emphasis on correct posture and temperature, early feeding, and minimum handling. With this and with his isolation policy we are in complete agreement. However, we then part company. Modern methods of neonatal monitoring are not used in Salisbury. Nothing is given intravenously. Ventilation and positive pressure devices are not used, nor is phototherapy. Apnoeic attacks are treated with funnel air and oxygen (presumably without monitoring the infant's blood oxygen tension).

Dr Hughes-Davies justifies his practice by claiming that neonatal complications were 'seldom met' and that his babies 'did well' at follow-up. The only data he presents concern first-week neonatal mortality. Then, on the basis of a number of unsatisfactory comparisons, he concludes that his results compare favourably with those achieved by 'more intensive and active intervention'. Furthermore he extols the economic benefits of his approach which requires less equipment, fewer staff, and allows nurses and doctors to get more rest! As one of us has just completed a study of paediatric staffing and equipment for newborn care on behalf of the BPA, we are conscious of the deplorable deficiencies that exist up and down this country. Unless countered, Dr Hughes-Davies's views may well seriously impede efforts currently being made to correct this sad state of affairs. It is this that prompts us to write and to compare the Salisbury figures with our own. Before doing so, we should like to discuss the various comparisons made by Dr Hughes-Davies. Firstly, he compared his results with those reported for England and Wales, the unjustified implication being that 'intensive care' is practised everywhere except in Salisbury. However, the national survey of newborn care referred to earlier shows conclusively that only a handful of the 252 special care baby units in this country have the necessary experienced resident staff and equipment to provide more than a token intensive care service, if that. Incidentally, in making his comparison of first-*week* mortality Dr Hughes-Davies failed to indicate in the caption to his Table 2 that the figures for England and Wales referred to the whole of the first *month* of life, not the first week. Similar criticisms apply to his comparison with 'Wessex neighbours' about whom no information is provided. Comparison is made between the mortality of very low birthweight infants in Salisbury, where presumably most if not all of such infants are *inborn*, and University College Hospital where, in contrast, the majority are *referred* from a wide metropolitan area. We would submit that no conclusion may be drawn from such a comparison.

We should like to compare the Salisbury figures with our own from Southmead Hospital. It should first be explained that although our intensive care service has been steadily improving since it was initiated in 1970–71 (Figure) and although we are now better provided for than most, we still have significant shortages in both staffing and equipment. The special care baby unit of 36 cots at Southmead serves the 4800 inborn infants and acts as a regional referral centre. Therefore many more problem cases may be expected than in Salisbury. Two statistics demonstrate this: the incidence of low birthweight and fatal congenital malformation were respectively 68 and 50% higher at Southmead in 1973 than the average for Salisbury, 1969–76. Thus, with similar quality of care the early neonatal mortality rate (NMR) for Southmead might be anticipated to be about 50% greater than that for Salisbury. In fact the reverse was the case. The NMR for Salisbury for the whole period 1969–76 was 9·3/1000, while that for our department in 1973 was 5·5/1000. The figures for low birthweight infants were 109/1000 for Salisbury and 36/1000 for Southmead; for infants in the birthweight group 1501–2000 g they were 167/1000 for Salisbury and 38/1000 for Southmead, while in that for the group 2001–2500 g they were 19·9 and 8·0/1000 respectively. Incidentally, it seemed reasonable to pool the Salisbury figures in view of the small annual numbers and the fact that 'the care of the babies was unchanged' during the whole period.

A fairer and even more striking comparison in favour of intensive care may be made if infants weighing <1000 g at birth and infants with fatal congenital anomalies are excluded from the analysis. If this is done then the remaining 'preventable' NMR for Salisbury was 5·8/1000 livebirths while that for Southmead in 1973 was 3·0/1000; by 1978 the Southmead figure had fallen to 1·7/1000. A final comparison needs to be made for babies of very low birthweights (500–1500 g). The NMR for 105 such infants in Salisbury was 505/1000 while that for the 49 similar infants at Southmead in 1978 was 224 or, if fatal malformations are excluded, 174/1000 (a survival rate of 83%).

If we assume that, on average, 600 000 infants are born in England and Wales each year, then it can be calculated that a country-wide application of the neonatal care advocated by Dr Hughes-Davies would lead to 2460 more 'preventable' early neonatal deaths each year among normally formed liveborn infants over 1 kg than would be the case if the 1978 Southmead standard were adopted instead. Nor does this figure take into account the fact that the Southmead figures were loaded with referred problem cases. In addition, as the late Professor W. C. M. Nixon wrote in 1963: 'Like an

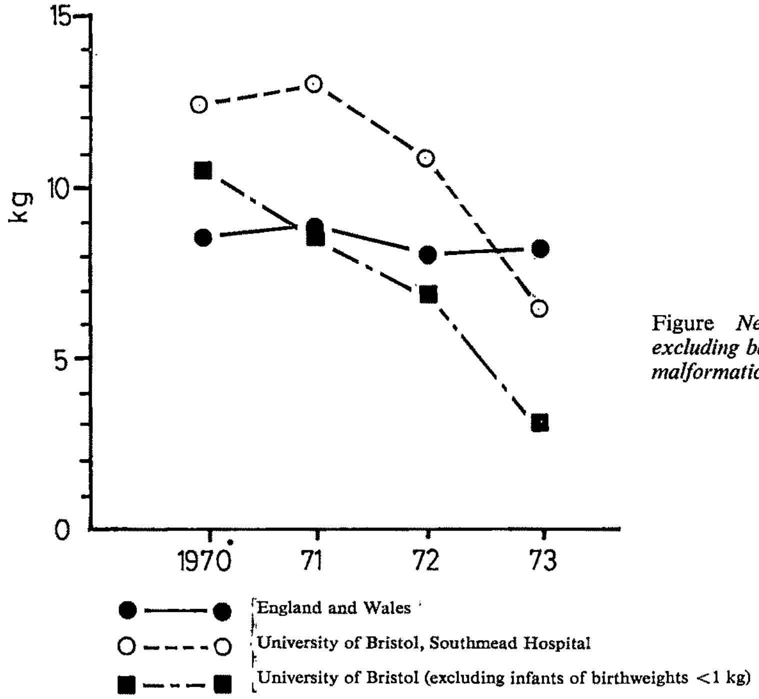

Figure *Neonatal mortality rates 1970–73, excluding babies with fatal congenital malformations.*

iceberg, we see only a proportion of the ill results, the deaths. But we must not forget the submerged and larger fraction, the near deaths and the harm which they cause'—*the long-term handicaps*. As to the cost–benefit of prevention, our admittedly amateur calculations suggest that the provision of good newborn care is likely to pay for itself at the very least 20 times over and perhaps 100 times or more.

In conclusion, we should like to make the following points: (1) We warmly support Dr Hughes-Davies's emphasis on the importance of the fundamental principles of keeping small sick infants warm and fed, of nursing them prone, and of handling them as little as possible. (2) We deplore and reject his denial of the benefits of modern intensive monitoring and therapy for infants that require such support. (3) We have some sympathy with his view that a great deal of intensive care *as currently practised* with inadequate staff and facilities may be counterproductive—although we have even more sympathy with the nurses and doctors who struggle on in spite of the difficulties. (4) Finally, we would agree with Dr Hughes-Davies when he stresses the critical importance of good antenatal and intrapartum care in reducing perinatal mortality.

P. M. DUNN AND B. D. SPEIDEL
Department of Child Health,
Southmead Hospital,
Bristol BS10 5NB

Dr Hughes-Davies comments:

The letter from Dr Dunn and Dr Speidel raises some interesting points.

The comparison of very small babies was, as stated, with those born in University College Hospital. I excluded those transferred because we do not know from what population they came. Paradoxically the figures suggest that the transferred babies did at least twice as well as those born on the spot, presumably because the tiny and the weak died before they could be moved; and it may be that this effect favours Southmead too. London has many more immigrants than Salisbury, and some of these babies are likely to be more mature for a given weight than ours; hence the breakdown by gestation in Table 4. I still think the comparison is valid enough to make the point that we have far to go in helping babies of <1000 g.

The Wessex neighbours were Basingstoke, Bournemouth, Dorchester, Portsmouth, Southampton, and Winchester. The first-week figures were not collected by me, but I was allowed to use the totals. Salisbury compared favourably with the others individually, and I am not sure why the comparison is rejected.

I had available only the 4-week national figures sufficiently broken down by weight, and I expected that the table would be read in conjunction with the text. If our monthly figures had been included there would have been little difference, although some babies may well have died at home or elsewhere without our knowledge. Those of <2500 g who died in the 2nd–4th weeks were: a 2400 g mongol with Dandy-Walker syndrome (at 4 weeks), a 2400 g baby with congenital viral pneumonia (in the 2nd week), a cot death of a 1420 g baby at home (in the 3rd week), and a quadruplet weighing 900 g who died from *Klebsiella* pneumonia (at 3 weeks).

Despite Dr Dunn and Dr Speidel's warning, the Southmead figures fail to distinguish between babies born there and elsewhere (or so I infer from the mention of problems from afar which is otherwise irrelevant). I agree with their submission that this invalidates further comparison, but I shall continue. The category 500–1500 g contains a mixture of babies, some with an excellent chance of survival and others with none, and without further breakdown it is meaningless. If their distribution matches that of Salisbury in 1974–76, there can have been no undeformed death > 750 g in 1978. Is this so? Or do they have more babies of 1400 g and fewer of 500 g because of transfer from outside? The advantage of selection to the receiving hospital is, of course, offset by a worsening of the figures in the referring hospital, unless both claim the baby in which case the regional figures will show a spurious improvement. A similar error of selection is produced by counting babies at the nursery door instead of at birth.

Even if figures are properly derived and presented raw by number, year, weight, and origin, they provide no basis for comparison unless the state of the babies coming into care is the same. This depends on the pattern of motherhood which perhaps changes uniformly throughout a wide region, and of obstetric care which shows much local variation and can change abruptly as doctors move and methods (whether alcohol drips or caesarean delay times) alter. Both Salisbury and Bristol show a similar decline in mortality over the years—the Salisbury figures corresponding to the lower University of Bristol line of the Southmead chart are 5·6, 8·9, 9·5, 7·4, 3·7, 4·2, 2·7, and 2·2 respectively for the years 1969–76. In Bristol the trend may be due to the institution of intensive care in 1970; but in Salisbury, where paediatric care has been held constant, the steady improvement over the years must be due to better mothers or to better care before birth. Incidentally this makes the pooling of figures over the years unreasonable. Even in 1976 it is likely that Salisbury which lacks senior registrars, had no convenient theatre or nearby outpatient clinics, and has insufficient fetal monitors, was handicapped compared with Bristol; but if comparison is to be made, it should be with the later years. I have already dealt with the likely bias among Southmead's lighter babies; for those from 2000–2500 g where transfers are less likely, our figures match (Southmead 8·0, Salisbury 9·5 per thousand for 1974–76, a statistically insignificant difference of about one baby in 7 years).

Perhaps a better approach is to look at the individual babies and ask why they died. This I attempted to do for babies over 1000 g in Table 3 by excluding those we could not or would not wish to save by reason of lethal uncorrectable deformity, tentorial tear proved at necropsy, or severe intrapartum asphyxia suggested by prolonged apnoea at birth. Again looking at 1974–76, there were 5 such deaths, one after operation elsewhere, and 2 in babies delivered far away without help and admitted moribund. This gives a paediatrically preventable NMR of 0·9/1000 which is not of course fairly comparable with Southmead's preventable NMR of 1·7 in 1978.

An administrator doomed to view the world through marks on paper, might estimate from the Southmead graph that, spread over the country, their methods would have killed 5000 babies in 1970–73. Having a profound distrust of vicarious statistics, and recognising Bristol's long record of distinction in the care of children, I know that this would be nonsense, as are most such computations. So much for the numbers game, by which we need set no great store.

Like modern rock climbing, intensive care has developed awesome techniques, which although sometimes of use to the scrambler, threaten to become an end in themselves, so that the best way to take a baby up Eiger appears to be by the north face. It is no longer entirely facetious to suggest that a patient with a heart attack sometimes needs intensive care to survive the effects of intensive care, and that those who succumb to this may more or less balance those who would have died if they had stayed quietly at home under skilled supervision after initial resuscitation. Whether this is true of newborn babies I do not know. Neither do Dr Dunn and Dr Speidel, but I hope they will take the opportunity to find out by subjecting some of their babies to the Salisbury usage (having first read my paper a second time to correct their inadequate summary of the method). In the meantime we should remember that truth does not come out of the mouth of a committee, and that the safest response to uncertainty is diversity. As Dr Dunn and Dr Speidel so kindly say, we have a lot in common, and of course research must continue, although perhaps it should not be mimicked too soon or too widely. But all nurseries really should divulge their results in proper form, if necessary in confidence, perhaps to Sir Cyril Clarke and Professor Neville Butler to whom our babies owe so much. And perhaps too they should end their day with a Litany—'From gastric oxygen, streptomycin, delayed feeding, and arterial thrombosis, Good Lord Deliver Us'—it will be a long one, and there is no reason to think it is not lengthening. I may even join it myself.

T. H. Hughes-Davies
Central Hospital,
Honiara,
Solomon Islands

Sir,

I should like to make some comments on the paper by Hughes-Davies (*Archives*, 1979, **54**, 59). I think there are several points that need to be made, in view of his allegations that neonatal intensive care is of little benefit.

Firstly, his figures are not as good as he would like to make them. For infants of birthweights 1001–1500 g, apart from one very good year in 1976 which all units get periodically, his figures are considerably worse than those quoted currently from neonatal intensive care units in the UK. Furthermore his figures for 1500–2000 g report a neonatal mortality which is again two to three times higher than that reported from such units. To compare with his Wessex neighbours is unjustifiable—clearly they also need better intensive care facilities, and to compare with England and Wales for the first *month* is again quite unsatisfactory. In addition there is much evidence to show that the overall standard of perinatal and neonatal care in this country is a disgrace.

Secondly, I find his Table 3 unsatisfactory. Prematurity is not a diagnosis I recognise between 1001 and 1500 g. I suspect all those 7 babies died from hyaline membrane disease (HMD)—untreated. Furthermore, column one in Table 3 only contains 12 babies, whereas 26 babies of this birthweight died. Some may have had lethal deformities, but presumably the majority died of intrapartum asphyxia. We have shown (Roberton and Tizard, 1975) that it is such small babies who suffer intrapartum asphyxia that suffer the most severe HMD, but many of these are salvagable in a neurologically intact state by modern techniques in neonatal intensive care.

Thirdly, I would hope that all paediatricians would now regard it as a completely unsatisfactory standard of care to provide face mask oxygen for very low birthweight babies without control of arterial oxygen tension.

One very important factor to consider when such data are provided is what are the obstetricians in his unit doing with women with major complications of pregnancy and seriously compromised fetuses at gestations of 28 to 30 weeks? Do they feel they have no alternative but to try to keep the pregnancy going for another week or two with subsequent intrauterine death, or do they in fact send such women to be delivered in a perinatal unit providing modern standards of intensive care? Many of us who run neonatal intensive care units know the latter practice is increasingly common where the local standards of neonatal care are inadequate.

Neonatal intensive care does save lives. The Table shows that neonatal mortality in Oxford was reduced by half over a 3-year period during which an adequate programme of intermittent positive pressure ventilation (IPPV) was instituted. The standards of care described by Dr Hughes-Davies may have been satisfactory in Salisbury, they may be satisfactory in the Solomon Islands, but I hope that all readers of the *Archives* will reject them as being unsuitable for the UK in 1979.

Table *Numbers of neonatal deaths, and infants surviving IPPV over 3-year period*

Year	*Neonatal deaths*	*Infants surviving IPPV*
1971	41	1
1972	28	9

Dr Hughes-Davies comments:

Some of the points made by Dr Roberton are covered in my reply to Dr Dunn. I agree that prematurity is an unsatisfactory diagnosis at any weight. Five of our 1001–1500 g babies so labelled were born in 1970 when I was in Saigon and I have no other details except that 3 were 28 weeks or less, and 2 were second twins; it is likely that babies were disturbed more then than in other years. Of the other 2, one, born in 1974, weighed 1020 g supposedly at 25 weeks and died at 4 hours after repeated apnoea; the other died at 24 hours in 1971 and weighed 1420 g; histology showed only atelectasis, and neither had HMD. Of the 26 babies dying in this weight range, 9 had prolonged apnoea at birth, 6 in 1971 or before, one in 1972, and 2 in 1974. They did not have HMD. One of the most striking features was the mildness of respiratory distress in babies handled gently in Salisbury (and in the Solomon Islands where I was pleased to meet a very fit baby now 14 months old who weighed 750 g at birth and who was cared for conservatively by Dr Ogatuti). Perhaps babies prefer pastures to battlefields—certainly their need for high concentrations of oxygen is rare, and its risks may be balanced by those of an indwelling arterial catheter which I am sure Dr Roberton would agree is the only worthwhile method of monitoring yet available. Even this is vitiated by a 10% leak from the ductus arteriosus.

No baby to my knowledge was transferred elsewhere either before or after birth except for surgery, and the distribution of weights matches the country as a whole. Patterns of intervention varied as they did elsewhere over the period, but our relations with the obstetricians were good, and I do not think our practices influenced theirs.

Of course intensive care saves lives; and of course it demands a price which can perhaps be justified in hospitals lucky enough to enjoy the skills of Dr Roberton. But I hope he will read my paper again. I have erred if he reads it as an attack on intensive care. It was simply an account of my reaction to practices current 13 years ago, which he suggests are still common today; and I hope he will regard the results as a control group for his own if he cannot bring himself to try the method. Dr Roberton's Table shows a fall in neonatal deaths about the same proportionately as occurred in Southmead and Salisbury and probably elsewhere in the first half of this decade; and, in the absence of an adequate library, I cannot comment on the number surviving IPPV which must depend on the number submitted to it. Again I would ask first for reliable figures; and second for a demonstration, perhaps in a single region, that Dr Roberton's methods can be as effective in less fortunate hands.

Hypopituitary dwarfism and breech delivery

Sir,

Recent investigations by Rona and Tanner (*Archives*, 1977, **52,** 197) show that breech delivery is a common occurrence in patients with idiopathic hypopituitary dwarfism.

We conducted a survey on the type of delivery in 118 patients with idiopathic growth hormone deficiencies (age range 4–18 years) and in 121 healthy control children.

Among the cases of hypopituitary dwarfism, 43 had isolated and 'total' growth hormone deficiency, 64 had isolated and 'partial' growth hormone deficiency (Priece and Tanner, 1976; Boscherini *et al.*, 1978), and 11 had multiple pituitary trophic hormone deficiencies.

The incidence of breech delivery was much higher in patients with hypopituitary dwarfism (19·6%), than in the control group (1·6%) (Fisher's exact probability test: $P<0\cdot01$). Moreover we observed that breech deliveries were slightly more common in patients with isolated and 'partial' growth hormone deficiencies, certainly more common in patients with isolated and 'total' growth hormone deficiencies, and were very common in patients with multiple pituitary trophic hormone deficiencies (Figure). The trend was significant when analysed by Armitage's χ^2 test ($P<0\cdot01$).

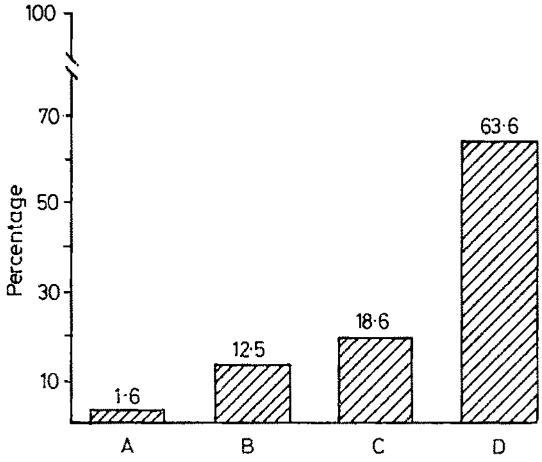

Figure *Incidence of breech delivery in patients with hypopituitary dwarfism. (A) Control group, (B) partial growth hormone deficiency, (C) total growth hormone deficiency, (D) multiple pituitary trophic hormone deficiency.*

The high frequency of breech delivery in our patients and the close relationship between the frequency of podalic presentation and the severity of functional pituitary impairment support the view that breech delivery plays an important pathogenetic role in idiopathic hypopituitary dwarfism.

Paediatric Ophthalmology Study Group

Sir,

This interdisciplinary study group on Paediatric Ophthalmology was founded by the late Dr Ronnie Mac Keith. It includes ophthalmologists, paediatricians, neurologists, psychologists, teachers, social workers, and others involved in the care of visually handicapped children. Its objectives are to further the knowledge of the subject, exchange ideas, and stimulate interest in this field to the eventual benefit of children who are visually handicapped. The group meets twice a year; in the autumn at the Newcomen Centre, Guy's Hospital, when formal papers followed by discussion are presented, and early in the year when visits are made to research units, special schools, or to any department concerned with the problems of paediatric ophthalmology. The present Convener is Dr Neil Gordon, Booth Hall Children's Hospital, and the organisation of the group is supported by the Spastics Society.

Book reviews

Atherosclerosis: Its Pediatric Aspects. Clinical Cardiology Monographs. Edited by W. B. Strong. (Pp. 330; illustrated + tables. £12.85 hardback.) Grune and Stratton: New York. 1978.

This monograph comprises a series of papers about the risk factors for atherosclerosis. This is a popular subject at the present time and it certainly is useful to have an up-to-date statement of the art. I do not think that the book contains anything very startling or new, but it is a good starting point for anybody who wishes to get into the field.

There is first a generally rather optimistic overview, which is summed up in the Foreword, where the first sentence concludes: '. . . the best available data suggest that if 11 known risk factors were controlled in adults, *only* 50% of the cases might be prevented' (my italics).

One of the most intriguing facets of atherosclerosis concerns its geographical pathology and the chapters from Newman and Strong and from Hames and colleagues in Georgia concentrate on this. Henry Neufeld contributes some more of his intriguing arterial pictures, which have much to do with the genetic and environmental determinants of atherosclerosis. Lipids, lipoproteins, hypertension, smoking, nutrition, and exercise are considered in some detail.

I found the most interesting chapter to be the one about atherosclerosis prevention in Arizona. Nobody knows whether such programmes will actually reduce the incidence of it, but as Henry McGill is reported to have said: 'Nobody has ever shown that high cholesterol levels, high blood pressure, or smoking is good for your health, nor has anyone demonstrated the benefits of obesity or sedentary living habits'.

I am glad to have this book and I hope that it will be available in the larger libraries. I think academic departments of paediatrics ought to possess it, but I would not advise every paediatrician to go out and buy his own copy.

C. G. D. BROOK.

Atlas of Abdominal Ultrasonography in Children. By G. F. Gates. (Pp. 283; illustrated. £16.50 hardback.) Churchill Livingstone: Edinburgh. 1978.

Although this book is entitled *Atlas of Abdominal Ultrasonography in Children*, it is much more than that. It is a summary of differential diagnosis and of the most appropriate and rewarding investigations that should be performed in abdominal disorders, with the emphasis on radioisotope and ultrasonic scanning.

The author is Associate Clinical Professor of Radiology and Director of the Department of Nuclear Medicine and Ultrasound in the Children's Hospital in Los Angeles, so it is easy to see why he has approached the subject of ultrasonography from this, the ideal point of view.

There are chapters on the liver and spleen, biliary system (including the pancreas), midabdomen, pelvis, and kidneys. The introduction gives the essential points that should be looked for by the referring clinician on the indications for ultrasonic scanning and the limitations of it, and there is useful and practical advice for those starting an ultrasonic scanning programme. The complementary nature of ultrasonic scanning to diagnostic radiology and radioisotope imaging is emphasised, and its noninvasive nature stressed, explaining its ready acceptance by most children. Much of the book is devoted to illustrations which are mainly of good quality, although the text is interesting and readable.

At £16.50 the book is a good buy for departments of diagnostic imaging. It can be recommended to all those who scan paediatric patients, to the referring clinicians, and those who are about to sit an examination in diagnostic imaging or who wish to bring themselves up to date with recent advances in this field.

BARBARA C. KING

Nutrition, Immunity, and Infection. Mechanisms of Interactions. By R. K. Chandra and P. M. Newberne. (Pp. 246; illustrated + tables. $22.50 hardback.) Plenum: New York. 1977.

The authors have addressed themselves to one aspect of clinical immunology that is currently exciting interest and consuming a good deal of effort in research and clinical immunology. They draw attention to the fact that perhaps a hundred million children suffer from kwashiorkor and that minor forms of nutritional deficiency must therefore be very much more common. It has been widely believed that malnutrition is associated with an increased hazard of infection, and so a scientific text examining this possibility more fully must be widely welcomed. Their book, which fills 233 pages including bibliography, is divided into 9 chapters. At the beginning a careful, detailed, and up-to-date account is given of the immunological resources of the developing human organism. There follows a full and helpful chapter concerned with the assessment of nutritional status including nutritional aspects of fetal life. The middle section of the book deals with the interactions between infection and immune responses, and the metabolic effects of infections. This section is detailed and is linked, as other sections are, to a full and up-to-date bibliography. Towards the end there is a section dealing with those topics in a comparative manner referring to research in nonhuman species, and finally, there are useful sections on the wider biological implications of infection, nutrition, and immunity, together with a comment on further research needs.

The book is well illustrated and contains a number of useful factual tables. It would perhaps have been helpful to have a numbered list of headings with the title of each chapter since each paragraph is carefully numbered. With this minor criticism the book can nevertheless be strongly recommended to clinical researchers and those who are interested in related subjects of immunology and nutrition. The book provides a very good framework and is not too expensive for purchase or too lengthy to read. It is to be hoped that the authors will be prepared to maintain the book through a number of editions for although it is now fully up to date one can imagine that in this expanding subject revision will be necessary within 3 or 4 years. This shows the value of the book rather than affords a criticism.

C. B. S. WOOD

Paediatric Cardiology. By R. H. Anderson and E. A. Shinebourne. (Pp. 616; illustrated + tables. £18.00 hardback.) Churchill Livingstone: Edinburgh. 1978.

This book is an account of the proceedings of the Second European Symposium sponsored by the British Heart Foundation and organised by the editors. The purpose of the symposium was to concentrate on some of the more important growing aspects of the diagnosis and management of congenital heart disease, and contributors from America and Europe were chosen for their special experience in the subjects covered. These of necessity tend to be rather restricted, so that the book in no way represents a comprehensive account of modern paediatric cardiological practice as its title might suggest.

As with all international symposia, the standard of contributions is variable. There is an excellent account of the new terminology in congenital heart disease and its relevance to the precise diagnosis of complex lesions, using the method of sequential chamber localisation which the editors themselves have done so much to promote during the last few years. Likewise, the sections on ventricular septal defect, Fallot's tetralogy, and atrioventricular canal defects, contain interesting material which is well presented. In particular, Rudolph's introductory review of ventricular septal defect in infancy is a small masterpiece of clarity and concise organisation of essential information. However, in other parts of the book, especially where the subject matter is more abstruse, both text and format tend to suffer from an unfortunate degree of repetitiveness. The free discussion that follows each major section, and which is generally of a high standard, enhances the interest and understanding of each subject.

Because of its specialised and selective content, this book cannot be recommended as a work of reference for undergraduates or noncardiological postgraduates. Nor will it be of value to general paediatricians. However, for those engaged in the challenging and fascinating task of diagnosing and treating infants with complex congenital cardiac defects it will provide a fund of valuable and up-to-date information.

T. A. H. ENGLISH

Reflux and Renal Scarring. British Journal of Radiology Supplement 14. By P. G. Ransley and R. A. Risdon. (Pp. 35; illustrated + tables. £3.60 (£3 to members of British Institute of Radiology) paperback.) British Institute of Radiology: London. 1978.

It might seem a difficult task to review an experimental study the results of which so closely accord with the reviewer's own clinical experience and views. Nevertheless it can be said without reservation that this supplement deserves the close attention of all those who are concerned with the clinical care of children with urinary infection or vesico-ureteric reflux (VUR), and with the prevention of renal scarring and its possible consequences.

The association of VUR, renal scarring, and urinary infection has been recognised for some time, but the mechanisms have been less clear and there remain a number of unexplained clinical anomalies—such as the child with VUR who has recurrent urinary infection but persistently normal kidneys. Hodson's pioneering experimental studies had confirmed that when VUR was induced in pigs, the development of renal scarring was confined to those areas of the kidney where intrarenal reflux (IRR) had been visualised. In this book Ransley and Risdon set out to investigate the relative importance of urodynamic factors, infection, and the morphology of the renal papillae in the development of such scars. The result was a carefully planned and controlled series of experiments presented clearly and readably and assisted with admirable diagrammatic, radiological, and histopathological illustration. The reasons for the choice of the experimental animal (piglet), and the precise techniques used, are also discussed succinctly.

The basic findings are summarised as follows: 'Segmental chronic pyelonephritic scarring in the young pig depends upon vesico-ureteric reflux of infected urine. Individual scars are formed at the sites of intrarenal reflux and this in turn is determined by the form of the renal papilla, some allowing intrarenal reflux and some preventing it.'

The morphology of the pig's kidney resembles that of the human in many respects and there is a close similarity between the induced and the naturally occurring renal scar. If the analogy between the experimental and clinical situation is to be pursued, then the implications of this study must include a reappraisal of the need for ureteric reimplantation and its timing, and an emphasis on the importance of urinary infection, its early diagnosis, and adequate treatment.

Paediatricians, urologists, radiologists, and pathologists, will all enjoy reading this book. So too will those who are excited by observing the emergence of convincing answers from a carefully planned study.

JEAN M. SMELLIE

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Phadebas RAST®
In-vitro test for atopic allergy.

THE HEINZ FELLOWSHIPS OF THE BRITISH PAEDIATRIC ASSOCIATION

H. J. Heinz Company Limited generously endows Fellowships in Paediatrics which the Nuffield Foundation administers in conjunction with the British Paediatric Association.

Two or three Fellowships will be offered each year, the number and type awarded in any one year depending on circumstances and the calibre of applicants available.

The types of Fellowship, which are open to men or women are:

A To enable a paediatrician from any part of the Commonwealth overseas to spend up to twelve weeks in the United Kingdom, meeting British paediatricians and seeing something of their work. Preference will be given to those recently established in an academic career who can arrange their visit to allow attendance at the Annual General Meeting of the British Paediatric Association in April 1980.

B Fellowship B scheme has been discontinued for the time being.

C To enable a paediatrician from the United Kingdom of Senior Registrar or Consultant status, but in the early years of professional life, to make a short working visit (up to three months) to a centre in a developing country, teaching or conducting research so as to benefit both fellow and hosts.

Applications for these awards must be received by the Nuffield Foundation not later than 31st December 1979.

Applications for C Fellowships can be accepted up to 31st January 1980.

The conditions for the Fellowships and application forms may be obtained from the Director of the Nuffield Foundation, Nuffield Lodge, Regent's Park, London NW1 4RS.

ARCHIVES OF DISEASE IN CHILDHOOD

The Journal of the British Paediatric Association

James Spence Medallist, 1979 489

Original articles

Physiological responses of the newborn infant to resuscitation *A. W. Boon, A. D. Milner, and I. E. Hopkin* 492

Metabolic and hormonal responses of low birthweight infants to intravenously infused calories not exceeding the maintenance energy expenditure *I. Rubecz, J. Mestyán, P. Varga, and Gy. Soltész* 499

Mycoplasma pneumoniae infection. A follow-up study of 50 children with respiratory illness *J. Y. Q. Mok, P. R. Waugh, and H. Simpson* 506

Normal children with large heads—benign familial megalencephaly *R. E. Day and W. H. Schutt* 512

Four families with immunodeficiency and chromosome abnormalities *D. C. A. Candy, A. R. Hayward, D. T. Hughes, L. Layward, and J. F. Soothill* 518

Effects of physical training on hormonal responses to exercise in asthmatic children *S. Leisti, M -J. Finnilä, and E. Kiuru* 524

Dubin-Johnson syndrome with some unusual features in a Chinese family *N. S. Lo, C. W. Chan, and J. H. Hutchison* 529

Carrier detection in Duchenne muscular dystrophy. Evidence from a study of obligatory carriers and mothers of isolated cases *J. R. Sibert, P. S. Harper, R. J. Thompson, and R. G. Newcombe* 534

Cytomegalovirus and blood transfusion in neonates *J. W. T. Benson, S. J. Bodden, and J. O'H. Tobin* 538

Comparative trial of manual and mechanical percussion technique with gravity-assisted bronchial drainage in patients with cystic fibrosis *M. Maxwell and A. Redmond* 542

Serum C-reactive protein test in diagnosis of septic complications of cerebrospinal fluid shunts for hydrocephalus *R. Bayston* 545

Change of reference style 548

Short reports

Two cases of perinatal listeriosis *M. H. Robertson, N. G. Mussalli, T. A. Aizad, J. M. Okaro, and G. S. Banwell* 549

Water intoxication by the oral route in an infant *A. Etzioni, A. Benderley, and Y. Levi* 551

Copper deficiency in a low birthweight infant *P. Yuen, H. J. Lin, and J. H. Hutchison* 553

Pulmonary candidiasis in cystic fibrosis *B. M. Jenner, L. I. Landau, and P. D. Phelan* 555

Effective treatment for rhinopulmonary mucormycosis in a boy with leukaemia *O. B. Eden and J. Santos* 557

Neonatal aspergillosis accompanying fulminant necrotising enterocolitis *H. H. Mangurten and B. Fernandez* 559

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42,** 109; 1973, **48,** 751; 1978, **53,** 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1,** 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Multiple copying of the contents of the publication without permission is always illegal.

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Phadebas RAST®
In-vitro test for atopic allergy.

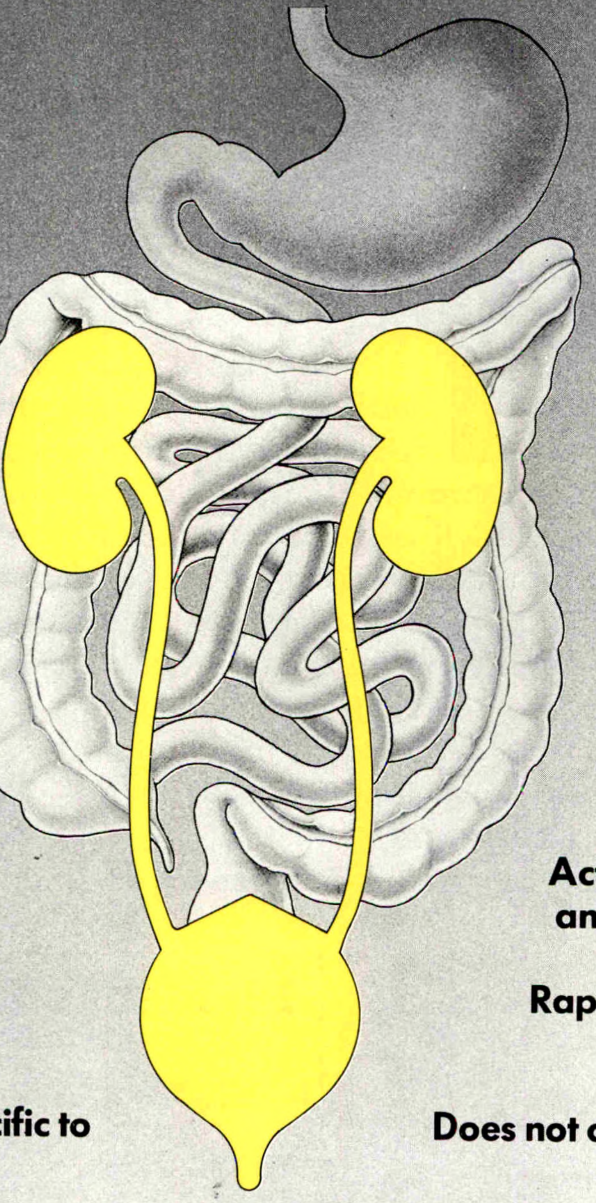
Furadantin Suspension

(nitrofurantoin)

To prevent lower urinary tract reinfection in childhood*



The only liquid form of nitrofurantoin.

For recurrent U.T.I. in childhood.

Bactericidal and specific to urinary tract.

Active in both urine and renal medulla.

Rapidly absorbed in G.I. tract.

Does not cause changes in gut flora.

Prescribing Information

Presentation Furadantin Suspension contains 25mg nitrofurantoin in each 5ml.

Action Furandantin Suspension contains nitrofurantoin, a broad spectrum antibacterial agent, bactericidal in renal tissue and throughout the urinary tract. After oral administration the nitrofurantoin is rapidly excreted in the urine, up to 45% being unchanged.

Uses Therapeutic. Cystitis, pyelitis, pyelonephritis; also post-operative infections of the genito-urinary tract, particularly after the passage of instruments and after prostatectomy. Furadantin Suspension is indicated in the treatment of urinary tract infections in pregnancy. The active ingredient, nitrofurantoin, has been in widespread use for over 23 years; this extensive clinical experience, and foetal studies in animals, have shown no evidence to suggest that nitrofurantoin may be a cause of congenital abnormality. However, it is recognised that caution should always be observed when prescribing for the pregnant patient.

Prophylactic. To prevent reinfection in susceptible individuals. As cover for catheterisation or instrumentation of the urinary tract.

Administration Furadantin Suspension is administered orally. The dose should be taken with each meal and at bedtime with food or milk.

Dosage Therapeutic. Adults 20ml 4 times daily.

Children

Bodyweight		Average age for weight	Dose to be taken 4 times a day
lb	kg		
10-30	5-13	3-30 months	2.5ml
30-50	13-23	2½-6 years	5ml
50-80	23-36	6-11 years	10ml
80-110	36-50	11-14 years	15ml

Prophylactic. One quarter to one half of therapeutic dose.

Contra-indications Infants under one month should not be given nitrofurantoin. Contra-indicated in patients suffering from severe renal impairment.

Side-effects and precautions Glucose-6-phosphate dehydrogenase deficiency. Peripheral neuropathy has rarely been reported after treatment with nitrofurantoin. Should numbness or tingling occur in any part of the body, treatment should be discontinued.

Nausea or vomiting may occasionally occur but this can be minimized or eliminated by taking the drug with food or milk, or reducing the dosage, but not below the adult equivalent of 200mg in 24 hours. Drug rashes and pyrexia with nitrofurantoin therapy have occasionally been reported.

Rarely a respiratory syndrome with bronchospasm and/or dyspnoea, cough and sometimes chest pain has been reported. These symptoms have occasionally been associated with transitory pulmonary infiltration or pleural effusion. Rarely, nitrofurantoin has been shown to cause hepatotoxicity.

Packaging Furadantin Suspension is supplied in bottles of 300ml.

Basic NHS cost 300ml bottle £2.18.

'Furadantin' is a registered trade mark.

PL 0364/0010 PA 170/5/3

James Spence Medallist, 1979

Kenneth William Cross

Kenneth Cross was educated at St Paul's School, London from 1930 to 1935 and then at St Mary's Hospital (London University) where he had won a Moran Scholarship.

After house appointments early in the war he served in the emergency medical service and was graded as a physician. He was in the Friends Ambulance Unit in China immediately after the war and returned to St Mary's in the physiology department under A. St. G. Huggett. At this time (1948) he started work on the ventilation of the newborn infant and was one of the first to apply objective physiological techniques to the clinical problem of resuscitating the newborn baby. He continued in the field of neonatal research thereafter.

In 1958–59 he was a visiting professor in the Cardiovascular Research Institute at San Francisco, directed by Dr Julius H. Comroe Jr, where he initiated neonatal research with a trio of young paediatricians, Marshall Klaus, William Tooley, and the late Kurt Weisser of Basle. From this small beginning grew what became one of the largest paediatric research groups in the USA.

In 1960 he became professor of physiology at The London Hospital Medical College, and in 1963 obtained a Medical Research Council Group to study respiration and metabolism in the newborn. Many of his publications have appeared in the *Journal of Physiology*, while in 1973 he organised for the Physiological Society the Joseph Barcroft Centenary meeting, and edited the account of that notable international symposium.

In presenting the James Spence medal to Professor Cross at the annual general meeting of the British Paediatric Association at York on 28 March 1979, the President, Professor O. H. Wolff spoke the following citation:

'Kenneth Cross is this year's James Spence Medallist. Our Association recognises the great contributions made to the advancement of paediatric knowledge by workers in allied disciplines. The Spence Medal has now been awarded on 18 occasions and among the medallists there are immunologists, geneticists, biochemists, physiologists, psychiatrists, in addition to paediatricians. But, I am afraid, we have not always been generous in openly acknowledging how much we paediatricians owe to our colleagues in the basic sciences. Without them the scientific basis of paediatrics would indeed be shaky. It is today my sad duty to have to remind you that when Kenneth Cross's name was first put forward for membership of the Association, the proposal was unsuccessful because, it was said, paediatricians saw no reason to include a physiologist among their members. By 1957 Kenneth's contributions to the physiology of the newborn were so many, so fundamental, and of such immediate relevance to paediatric practice, that at last he was elected a member. It is good that today we can make amends for our earlier lack of vision and give Kenneth the highest award of our Association. Kenneth has not had an easy professional life; paediatricians were slow to recognise the importance of his work for paediatrics, and physiologists found it impossible to believe that fundamental work could be done on the human newborn. At the same time as the first proposal for membership of the BPA was turned down, Kenneth

was told by his professor at St Mary's that it was time he stopped playing about with babies and got down to some proper physiology.

'Fortunately Kenneth is tough and these rebuffs further inspired him and stimulated his scientific curiosity and inventiveness, and his papers on neonatal respiratory physiology, written with clarity and economy of words, continued to be a stimulus to all of us. Even physiologists have over the years recognised the great merit of Kenneth's work and I believe that he may even have succeeded in persuading them that the human neonate, despite all his imperfections, is not to be despised as an experimental subject. The neonatal rat, guinea-pig, rabbit, pig, and lamb are no longer the only heroes on the stage of perinatal physiology. Accordingly, last year, Kenneth was invited to give the annual review lecture of the Physiological Society.

'Kenneth is tough, not only in spirit, but also physically. A Rugby football player of exceptional skill, he was admitted to St Mary's Medical School on a Rugby Scholarship. He drives an open car in all weathers and cannot understand why, during the arctic conditions of this winter, and despite rail strikes, some of his friends were a little reluctant to accept his offers of a lift.

'As head of his academic department, Kenneth is known for his personal concern for the problems of all members in his department and for his complete fairness. He can be firm when the occasion demands but he is no disciplinarian. In particular, he objects to being called 'Sir' by the more attractive girl students. I cannot tell you how he likes best to be addressed by them. He is respected and revered by his department, but unlike many academics who are prepared to give of their all for the benefit of their *own* department but show little concern for the welfare of the whole medical school or university, Kenneth has a wider sense of responsibility. It is, therefore, not surprising that his colleagues elected him Chairman of the Academic Board, and that among many other commitments he serves the British Council on its Medical Advisory Committee. Committees benefit greatly from his wisdom, delightful dry sense of humour, capacity for constructive criticism, and his willingness to make the needed unpopular remark.

'As a teacher, he has given much to paediatricians, many of whom have had the opportunity during their period of training, of carrying out research in his department. Some of them have been inspired by Kenneth to continue in paediatric research. Others have returned to clinical paediatrics with their clinical focus sharpened by the experience. Specifically I may mention the imaginative registrar rotation scheme which Kenneth established with his colleagues, Richard Dobbs, Tony Jackson, and Bertie Webb of Taunton, and in which the registrar spends one out of three years in neonatal research in Kenneth's department. Clinicians enjoy working with Kenneth, in part because he has much clinical experience gained during the war years as physician, including the period spent with the Friends Ambulance Unit in China.

'There is a particular interest of Kenneth's which should be mentioned. Physiologists who use human beings as subjects for their experiments have given much thought to the ethical principles of such research. Claude Bernard in 1865 realised clearly that data obtained from experiments on human beings are essential if the results are to be applied safely to the practice of clinical medicine. But Bernard warned that experiments, however interesting for science and potentially beneficial for the health of others, are not justified if they bring a degree of danger to the subject of the experiment. Robert McCance, the James Spence Medallist of 1961, in a splendid essay on perinatal physiology, points out that during the closing years of the last century and the first 25 years of this, physiologists such as Haldane and Barcroft carried out experiments on humans which would not have satisfied Bernard's criteria because there was some risk. However, these great physiologists, and a little later McCance himself and Widdowson, experimented on themselves and their colleagues. In his work with the newborn Kenneth insists on the strictest ethical criteria and Claude Bernard would have approved. He never sedates a baby in order to facilitate the investigation, he likes the mother to be present during the experiment, and when wishing to obtain the mother's permission for an experiment on her normal baby he does not use the subterfuge that the experiment might help her baby. At the same time he has no doubt, and has convinced all of us, that research on the newborn is an essential ingredient of paediatric research aimed at the improvement of child health.

'In 1974 at the Royal College of Physicians of London he summarised his views on these important matters in a Bertram Louis Abrahams Lecture entitled 'Investigating the newborn infant: the ethical imperative'. The Medical Research Council has been slow in recognising the importance of paediatric research, and facing up to the ethical problems of such research. I am hopeful that the attitude of the MRC is beginning to change in this respect, and if I am right then much of the credit for this enlightment will go to Kenneth who has been engaged in lively debate with the MRC for some time.

'My brief remarks will have made it clear that, like most original minds, Kenneth has had to overcome obstacles. Fortunately he is a fighter. Such a man needs even more than most of us a wife with whom he can share the exasperations arising from professional conflicts or who on other occasions is ready to put up with an irritable temper resulting from the battles of the day. Sheila is all this to Kenneth and so much more. Her own contributions to paediatrics are considerable, and she even finds time to serve our Association with distinction on Council and as Regional Representative. Perhaps from time to time she too comes home in the evening ready to share *her* worries with Kenneth. We wonder who speaks first?

'And now Kenneth may I give you this year's James Spence Medal.'

Physiological responses of the newborn infant to resuscitation

A. W. BOON, A. D. MILNER, AND I. E. HOPKIN

Department of Child Health, and Nottingham City Hospital,

SUMMARY Lung ventilation, endotracheal, and intraoesophageal pressures were measured during standard resuscitation of 20 asphyxiated babies born by caesarean section. The most common response to resuscitation was the production of a large positive intraoesophageal pressure. An opening pressure $>2\cdot0$ kPa was required to expand the lungs of most of these babies. The need for resuscitation was associated with prolonged maternal anaesthesia before delivery.

Endotracheal intubation and IPPV have for many years been the standard methods of resuscitating severely asphyxiated newborn infants. The aim is to expand and ventilate the lungs and to stimulate the infant into spontaneous respiration. Few attempts have been made to evaluate this technique or to study its effects on the neonate. Cross *et al.* (1960) showed that lung inflation in the neonatal period often produces reflex inspiratory efforts—such as, Head's paradoxical reflex. However, Hull (1969) demonstrated that during resuscitation the most common initial response to lung inflation is a reflex expiratory effort.

Pressure and volume studies on isolated newborn lung preparations have demonstrated an 'opening pressure' which has to be exceeded in order to expand the lung (Agostini, 1959; Gribetz *et al.*, 1959; Craig, 1963; Gruenwald, 1963; Rosen and Laurence, 1965). However, Karlberg showed that some spontaneously breathing babies are able to expand their lungs with a small opening pressure (Karlberg and Koch, 1962, Karlberg *et al.* 1962). More recently, Milner and Saunders (1977) showed that this is the most common pattern of lung expansion at birth. We therefore wanted to study the response of the newborn infant to resuscitation and to find out if an opening pressure was exhibited in the lungs of babies requiring resuscitation.

Method

Apparatus. The apparatus used was a Vickers resuscitation trolley with a spring-loaded valve set at 30 cmH$_2$O (2·94 kPa) in the inspiratory line. Oxygen was delivered at a rate of 3 l/min (0·05 l/second) via a modified T-piece (Fig. 1). Inflation pressure was measured using a strain gauge pressure transducer (SE Labs SEM 4–86). Intrathoracic pressure changes were measured using an 8 FG water-filled catheter perfused at a rate of 1 ml/hour using an infusion pump (Sandoz infusion pump). Tidal flow was measured across a pneumotachograph using an Elema-Schönander differential pressure transducer (EMT 32C). The flow signal was fed through an electronic integrator to produce the tidal volume. The oesophageal and inflation

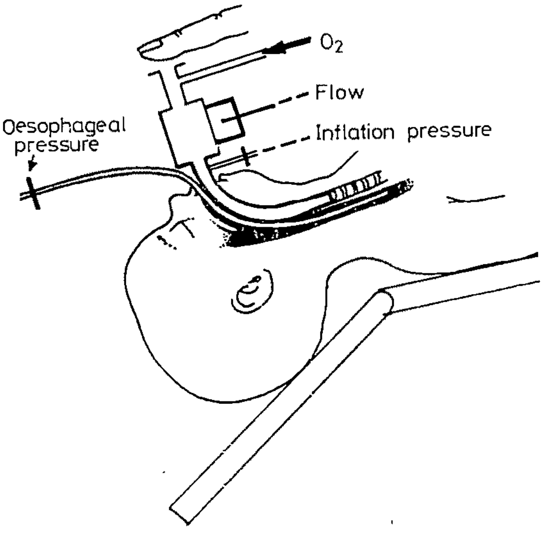

Fig. 1 *Diagrammatic representation of modified T-piece.*

Department of Neonatal Medicine and Surgery, Nottingham City Hospital
A. W. BOON, research fellow
I. E. HOPKIN, research sister
Department of Child Health, Nottingham
A. D. MILNER, reader in child health

pressures were calibrated against a water-filled manometer at the end of each run. The flow was calibrated using a rotameter and the tidal volume by injecting a known volume of air through the T-piece. The signals were transferred via an amplification system (SE Emma) to a 4-channel FM tape recorder (SE 84) and simultaneously displayed on a multichannel oscilloscope (SE Labs SEM 430).

Technique. The baby was placed on the resuscitation trolley immediately after delivery. Standard indications for resucitation were used—that is, the infant was apnoeic with a falling heart rate, hypotonic with no response to oropharyngeal suction, and a blue or white colour (Apgar score 3 or less).

A Warne's 14 FG neonatal tube was used routinely. The oesophageal catheter was passed orally while withdrawing the laryngoscope. The tube was passed to a distance of 13 cm from the lips so that the end lay in the lower third of the oesophagus (Milner *et al.*, 1978a). The baby's lungs were inflated at a rate of 30–40/min using an inflation time of approximately 1 second.

Data analysis. The data were analysed in two ways. The output from the tape recorder was fed into a 6-channel recorder with ultraviolet-sensitive paper (SE Oscillograph Se 3006). The inflation pressure and tidal volume signals were also played through an X–Y plotter (SE 225 Mark II) at 25% of the recording speed in order to construct pressure-volume loops of each lung inflation.

The frequency response of the system was assessed by mounting the oesophageal catheter and T-piece with endotracheal tube in a bung which was sealed in a 3-litre container. The open end of the T-piece was occluded and one of the tubes from the pneumotachograph was clamped off. The response characteristics were first determined by injecting 20 ml air rapidly via the T-piece into the container. The response times of the volume and inflation pressure signals were identical. As the limiting factor was the rate of injection of air, a sudden rise in pressure was achieved by bursting an inflated rubber balloon within the container. The 63% rise time of the pneumotachograph and inflation pressure systems were identical at 6·2 milliseconds giving a damping of 3 dB/octave at 25·7 Hz. The 63% rise time of the oesophageal pressure system was 13·2 milliseconds producing a 3 dB/octave attentuation at 11·7 Hz.

Subjects. Recordings were made in a total of 20 asphyxiated neonates born by lower segment caesarean section at a mean birthweight of 3·06 kg and gestation of 39 weeks. The Table gives the clinical details of the infants; 15 of them were delivered by elective caesarean section and 5 by emergency caesarean section. After preoxygenation, general anaesthesia was induced with thiopentone and suxamethonium. Anaesthesia was maintained with nitrous oxide and oxygen, with the addition of halothane in 9 cases, atropine in 4, and pancuronium in 4. Twelve of the babies had gasped or cried before becoming apnoeic.

*Emergency segment caesarean section, LSCS=lower segment caesarean section, R=rejection response, H=Head's paradoxical reflex.

These subjects were matched for birthweight and gestation with 23 babies born by lower segment caesarean section who did not require resuscitation at birth. The project was passed by the North Nottingham ethical committee.

Results

Responses to lung inflation. The responses of the baby to the first 3 inflations were analysed. In some instances more than one response was seen, therefor the responses add up to more than 60.

Rejection response

The most common response to lung inflation was a large positive intraoesophageal pressure—that is expiratory effort of up to 11 kPa (Figs 2 and 3). This response was seen with 37 inflations. The positive pressure ranged from 13–114 cmH_2O (1·27–11·18 kPa) with a mean of 63·9 cmH_2O (6·26 kPa). This response by the baby frequently caused expulsion of gas from the lungs while the inflation pressure was maintained (Fig. 3).

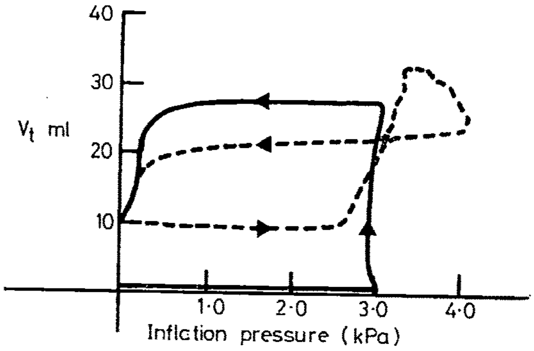

Fig. 3 (*Case 9*). *X–Y plot of inflation pressure against volume. In this and in subsequent X–Y plots, the 1st breath is represented by a solid line and the 2nd by a dashed line. During the 2nd inflation, gas was expelled from the lungs by the baby's 'rejection response'.*

Head's paradoxical reflex

On 15 occasions the infant responded to lung inflation with an inspiratory effort (negative oesophageal pressure)—that is, Head's paradoxical reflex (Figs 4 and 5). The negative pressure produced ranged from 3·6–48cmH_2O (0·35–4·70 kPa) with a mean of 20·1 cmH_2O (1·97 kPa). These inspiratory efforts often produced a fall in inflation pressure, sometimes resulting in negative endotracheal pressures of up to 30 cmH_2O (2·94 kPa) despite a biased flow of 3 l/min.

Passive inflation

On 17 occasions the baby's lungs were inflated with no active change in the oesophageal pressure. The pressure change in these instances was merely being transmitted across the lung (Figs 6 and 7).

On two occasions there was no oesophageal pressure change and no oxygen entered the lungs (Fig. 8).

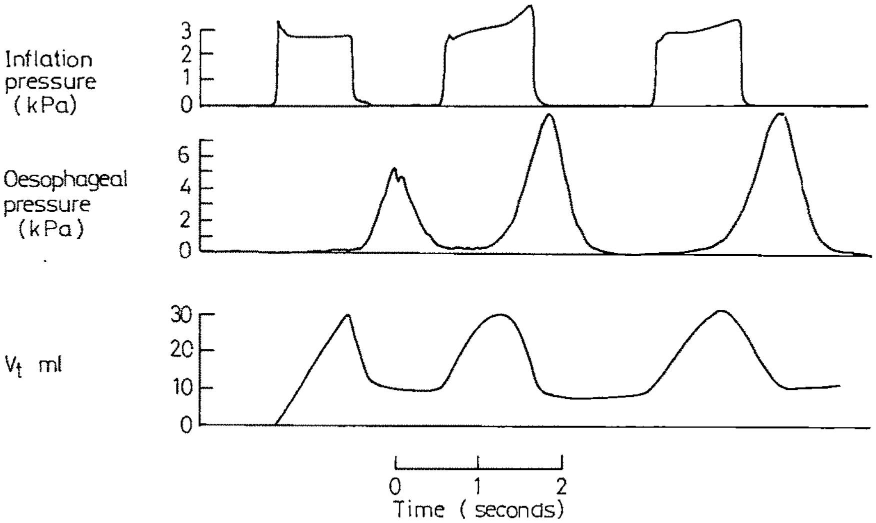

Fig. 2 (*Case 9*). *Inflation pressure, oesophageal pressure, and tidal volume* (V_t) *plotted against time, showing a 'rejection response' to lung inflation. Preinflation oesophageal pressure has been arbitrarily chosen as zero. The baby formed a functional residual capacity* (*FRC*) *of 10 ml.*

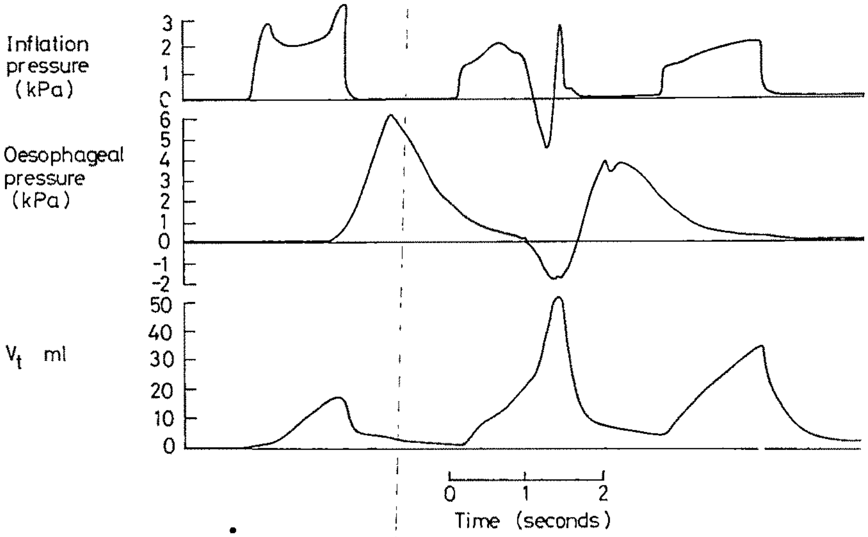

Fig. 4 (*Case 14*). *'Longitudinal trace' showing a rejection response to the 1st inflation with a Head's paradoxical reflex and rejection response to the 2nd inflation. Note the pronounced swings in inflation pressure.*

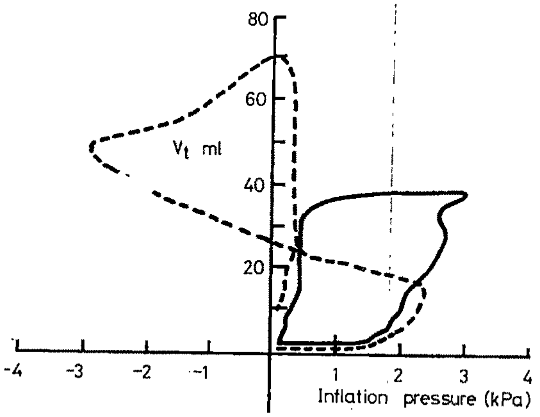

Fig. 5 (*Case 6*). *X–Y plot of inflation pressure against volume. The 2nd inflation was associated with a Head's paradoxical reflex and a pronounced increase in the volume of gas entering the lung. Note the low opening pressure of 1·5 kPa unlike that in Fig. 3.*

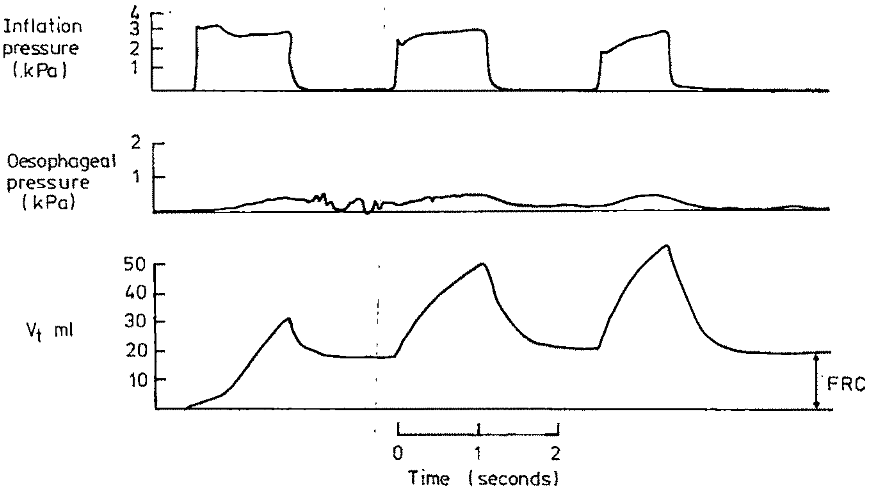

Fig. 6 (*Case 10*). *'Longitudinal trace' showing small passively transmitted changes in oesophageal pressure with each inflation.*

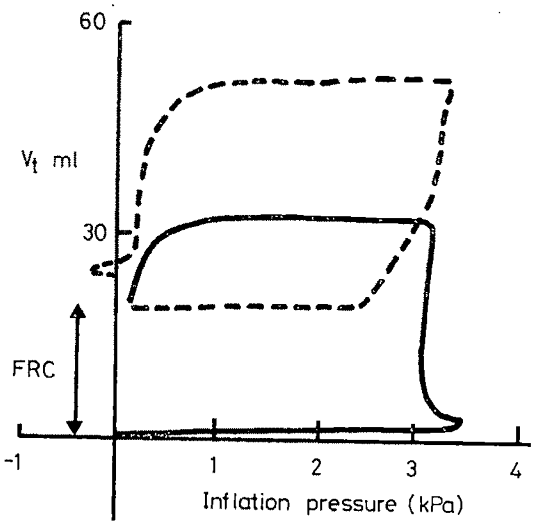

Fig. 7 (*Case 10*). *X–Y plot of the same baby as in Fig. 5. Again, there was an opening pressure in excess of 3 kPa.*

Inflation pressures and volumes during resuscitation. It was only possible to construct pressure/volume loops in 12 of the 20 babies. In the other 8 babies, the initial volume trace was unsatisfactory because of integrator drift and had to be obtained by integrating tidal flow from the tape recordings. Of the 12 babies on whom full data were available, 10 required an opening pressure of 2·0 kPa or more (mean 2·69 kPa) in order to expand their lungs (Figs 3 and 7). Rather surprisingly, 7 of this group had gasped before becoming apnoeic. In 2 infants lung expansion started with a pressure of 1·5 in one and 1·3 kPa in the other (Fig. 5).

Factors affecting the response to lung inflation. The intubated group of babies was compared with 23 matched controls who had a mean birthweight of 3·24 kg and gestation of 39·7 weeks. There was no significant difference in the indication for caesarean section or anaesthetic agents given to the mothers. However, the time from induction of anaesthesia to delivery of the baby was significantly shorter in the control group than in the intubated group (7·82 compared with 10·85 minutes, $P<0·02$). Furthermore, the longer the interval between induction of anaesthesia and delivery of the baby, the fewer the active responses to lung inflation produced by the baby. However, whether the baby had gasped or cried before becoming apnoeic did not predict the baby's response.

Discussion

This study confirms the work of Hull (1969) that the most common initial response to lung inflation is a reflex expiratory effort. It is possible that this large positive intrathoracic pressure represents a cough or a cry, although this is somewhat unexpected in an infant who has previously made little or no response to mucosal stimulation or tracheal intubation. It is obviously impossible to identify, without complicated electromyography, whether this is a cough or cry when the baby is intubated. Only three groups of lung mechanoreceptor are known to be stimulated by lung inflation: (1) pulmonary stretch

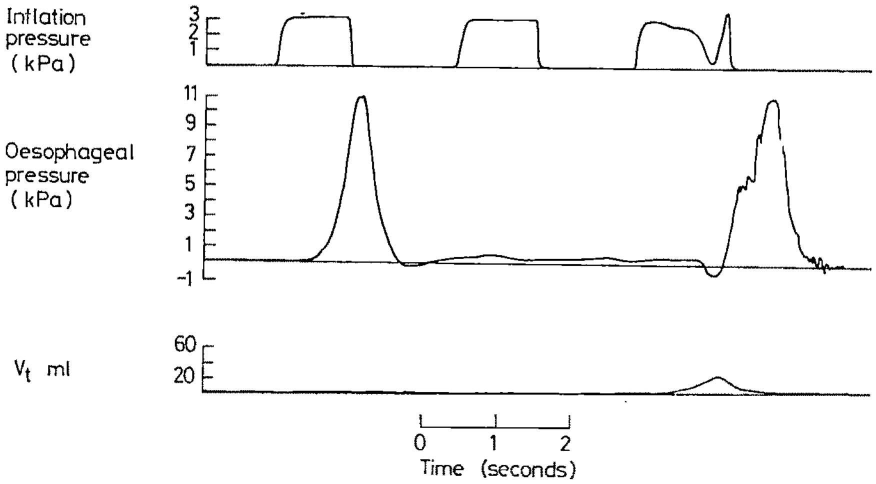

Fig. 8 (*Case 8*). *Longitudinal trace of a baby who showed all four types of responses to the first 3 inflations.*

receptors, which inhibit respiratory activity; (2) nonmyelinated vagal fibres responding to chemicals and large lung inflations to cause apnoea and rapid shallow breathing; (3) lung irritant receptors which normally cause a gasp (Coleridge *et al.*, 1965; Mills *et al.*, 1970; Sellick and Widdicombe, 1970). However, direct stimulation of the irritant receptors in newborn infants frequently causes apnoea or slowing of respiration (Fleming *et al.*, 1978). It is of interest that reinflation of a collapsed lung in healthy adults sometimes causes a cough (Burger and Macklem, 1968). It seems possible that this response is mediated via pulmonary irritant receptors.

Whatever the mechanism of the response, it was seen less often in the more severely asphyxiated babies and in those infants in whom there had been a particularly long interval between the induction of anaesthesia and delivery of the infant. It is interesting that spontaneously breathing babies who were not intubated also commonly produce large intrathoracic pressures on their first expiration (Karlberg *et al.*, 1962; Milner and Saunders, 1977). It is therefore unlikely that this effect is merely caused by the stimulus of cold gas on the respiratory epithelium.

Like Hull (1969) we have shown that Head's paradoxical reflex is seen less often in the initial lung inflation during resuscitation. It was of interest that the baby's own inspiratory efforts were often much more efficient in causing lung expansion than the inflating pressure (Fig. 4). It is not possible to say whether these responses are those of the normal asphyxiated neonate or whether there has been a modification of the response caused by the anaesthetic agent used.

Despite using what is normally accepted as an adequate flow rate of oxygen of 0·05 l/second (3 l/min) (Hull, 1969; Robinson, 1977), the baby's own inspiratory efforts frequently produced large fluctuations in the inflation pressure. It is possible that these large and rapid pressure swings may predispose the infant to develop a pneumothorax and for this reason it may be that higher flow rates of oxygen should be used to lessen this possibility.

It appears from these data that, unlike spontaneously breathing infants, babies requiring resuscitation at birth exhibit an opening pressure remarkably similar to 20 cmH_2O (1·96 kPa) calculated on theoretical grounds by Avery and Mead (1959) and found by workers inflating isolated lungs (Agostini, 1959; Gribetz *et al.*, 1959; Craig, 1963; Gruenwald, 1963; Rosen and Laurence, 1965). It is unlikely that the opening pressures we demonstrated are artefactual, as the frequency response of the inflation pressure and pneumotachograph systems was identical.

One possible reason for this opening pressure difference between spontaneously breathing and resuscitated babies may be that the baby's own efforts are more efficient at expanding the lungs as the force is being applied from all around the lungs.

Another factor which may account for the higher opening pressures in resuscitated babies may be that they were all born by lower segment caesarean section and therefore had not benefited from the effects of vaginal delivery in expressing liquid from the lungs (Milner *et al.*, 1978b) or from any other changes as the baby passes down the birth canal. It is unlikely that the pressure differences are due to the presence or absence of surfactant as none of the resuscitated babies developed any respiratory distress.

To try to clarify this difference we now intend to study vaginally-born babies requiring resuscitation at birth.

Conclusion

We feel it is important to state that there is still no way of predicting clinically which apnoeic babies are severely asphyxiated and whether they will produce active responses to resuscitation. Furthermore, babies who had cried or gasped at birth did not appear to differ from the group as a whole and sometimes produced no responses (for example, Cases 4 and 10). Intubation and IPPV should therefore continue to be the standard method of resuscitating apnoeic neonates.

We are grateful to Professor D. Hull for advice, and to the obstetric and theatre staff of the maternity unit at the City Hospital for help. This study was supported by an MRC grant.

Metabolic and hormonal responses of low birthweight infants to intravenously infused calories not exceeding the maintenance energy expenditure

I. RUBECZ, J. MESTYÁN, P. VARGA, AND GY. SOLTÉSZ

Department of Paediatrics, University Medical School, Pécs, Hungary

SUMMARY Eight low birthweight infants were studied for their metabolic and hormonal responses to intravenous alimentation when the caloric input was varied. The study was made during three consecutive 12-hour periods, when solutions of glucose, glucose and amino-acids, and glucose and amino-acid and lipids were successively infused. Hypertonic glucose led to a fall in plasma free fatty acids and amino-acids. Supplementation with an amino-acid mixture increased the concentration of amino-acids but not above the fasting level. Thus, hypertonic glucose was an effective means for avoiding hyperaminoacidaemia. Blood urea was little changed, also indicating satisfactory use of amino-acids. The number and distribution of calories infused throughout the third 12-hour period, when lipid was infused, were also important factors contributing to the avoidance of hyperaminoacidaemia. The caloric needs of low birthweight infants kept at neutral temperatures should be individually assessed in the light of recent data. The administration of an unnecessarily large load of calories and nutrients to parenterally-fed infants can thereby be avoided.

Knowledge of the caloric expenditure of the newborn infant, and of the factors which may alter it, is essential when alimentation is given by the parenteral route. Thus, if preterm infants <1500 g are fed intravenously using conventional estimates of maintenance energy expenditure, an excessive caloric load may be imposed leading to dangerous complications. These estimates often fail to take account of the fact that maintenance caloric requirement in the neonatal and postneonatal periods varies greatly according to weight, and gestational and postnatal ages (Mestyán *et al.*, 1968; Rubecz *et al.*, 1974; Rubecz and Mestyán, 1975). In view of this, we investigated the changes in the levels of the main plasma metabolites after infusion of nutritive mixtures with a low caloric value appropriate to the relatively low energy needs of low birthweight infants. The results may serve as a basis for further studies to define the caloric aspects of total parenteral nutrition in such infants.

Materials and methods

Infants. Eight low birthweight infants (2 appropriate for and 6 small for gestational age), in whom early oral feeding had failed, were infused with nutritive solutions for 36 hours. The mean gestational age was 32 weeks (range 28–35) and the mean birthweight 1362 g (range 900–1930). The average postnatal age at which parenteral feeding began was 18 hours. Clinical data, the volume of the nutritive solutions, and the calories and amounts of glucose, amino-acids, and lipid infused are summarised in Table 1.

Infusions. The design of the short-term IV feeding was as follows: (1) 10% glucose was given for 12 hours; (2) during the second 12-hour period 10% glucose with 2·7% crystalline amino-acids (Aminosol 2400: Vitrum, Stockholm) was infused; (3) thereafter in addition to the glucose and amino-acid mixture, 10% lipid solution (Intralipid: Vitrum, Stockholm) was infused by a second pump connected through a Y-connection. In this third 12-hour period when a mixture of the three main nutrients was given, care was taken not to exceed appreciably the maintenance energy expenditure. The supplementation of glucose

1 kcal ≈ 4·2 kJ.

as the basic caloric source, first with amino-acids and then with fat emulsion, represented a short-term alimentation programme with increasing caloric input and changing composition of the nutritive mixture. In brief, the study consisted of three consecutive 12-hour periods during which solutions containing glucose, glucose and amino-acids, and glucose and amino-acids and lipids, were infused.

Chemical and hormonal monitoring. Blood samples were drawn through an umbilical venous catheter before IV nutrition and at the end of each infusion period. The following metabolites were measured: glucose (Pryce, 1967), free fatty acids (Dalton and Kowalski, 1967; Laurell and Tibbling, 1967), lactate (Huckabee, 1958), α-amino-nitrogen (Rubinstein and Pryce, 1959), and urea (Ceriotti, 1971). In 6 infants the plasma concentrations of 17 individual amino-acids were also determined using a Beckman automatic amino-acid analyser. Plasma insulin and growth hormone were estimated (Hunter and Greenwood, 1962; Hales and Randle, 1963). Means and standard errors were calculated, and significance was estimated by the paired Student's *t* test.

Results

Response of blood glucose, lactate, and plasma FFA. Fig. 1 shows that the concentrations of glucose at the end of the three infusion periods were higher than the control level ($P<0\cdot01$ and $<0\cdot05$). The greatest rise was during the first 12-hour period when only 10% glucose was infused. Thereafter the addition of an amino-acid mixture to 10% glucose resulted in a fall in blood glucose, which remained still significantly above that of the preinfusion level ($P<0\cdot05$). Further supplementation with 10% lipid solution did not greatly influence blood glucose concentration which remained near the level of the end of the glucose and amino-acid period.

The mean concentration of plasma free fatty acids (FFA) fell in response to 10% glucose but, owing to the large individual variation of the fasting level, the fall was not significant. The infusion of amino-acids in addition to glucose caused a further decrease in the plasma FFA. Supplementation with 10% lipid solution, as expected, was associated with a pronounced rise in FFA concentration ($P<0\cdot01$).

Mean blood lactate was slightly raised by the end of the 10% glucose period. Supplementation with amino-acids and fat emulsion induced a gradual fall in blood lactate. However, its concentration by the end of the third infusion period, owing to the large variation in the starting values, was again not significantly lower than that before IV nutrition.

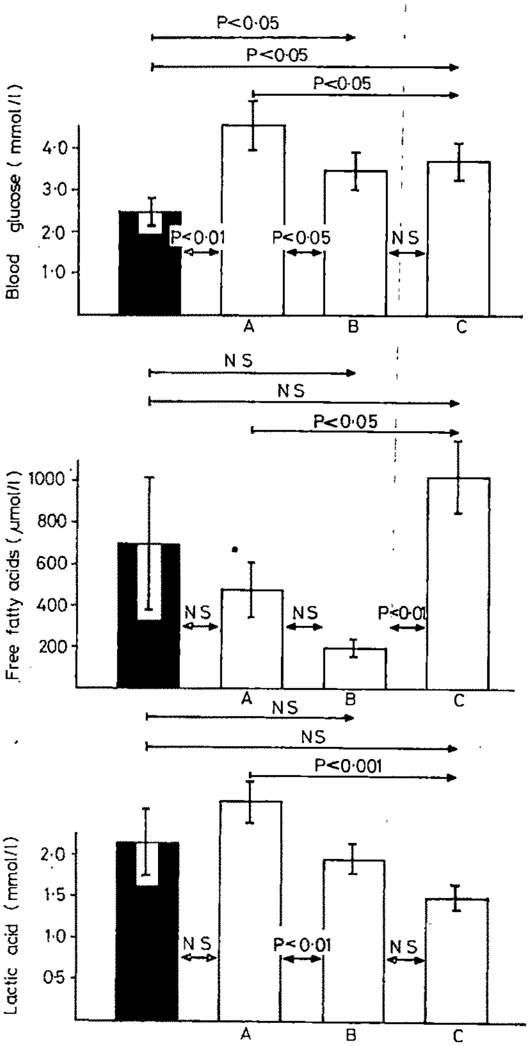

Fig. 1 *Response of blood glucose, free fatty acids, and lactic acid to infusions of* (*A*) *10% glucose,* (*B*) *10% glucose + 2.7% amino-acid, and* (*C*) *10% glucose + 2.7% amino-acid + 10% lipid.*

Changes in the plasma α-amino-nitrogen, urea, and amino-acid pattern. The changes in α-amino-nitrogen and urea content of the plasma are shown in Fig. 2. The mean level of α-amino-nitrogen fell significantly in response to 10% glucose ($P<0{\cdot}05$), but regained the fasting level when an amino-acid mixture was added to glucose. Further supplementation with 10% lipid solution did not affect the level, which remained at the fasting value.

Mean urea nitrogen was not greatly affected, with only a slight tendency to rise during the second and third 12-hour periods when the amino-acid mixture was given.

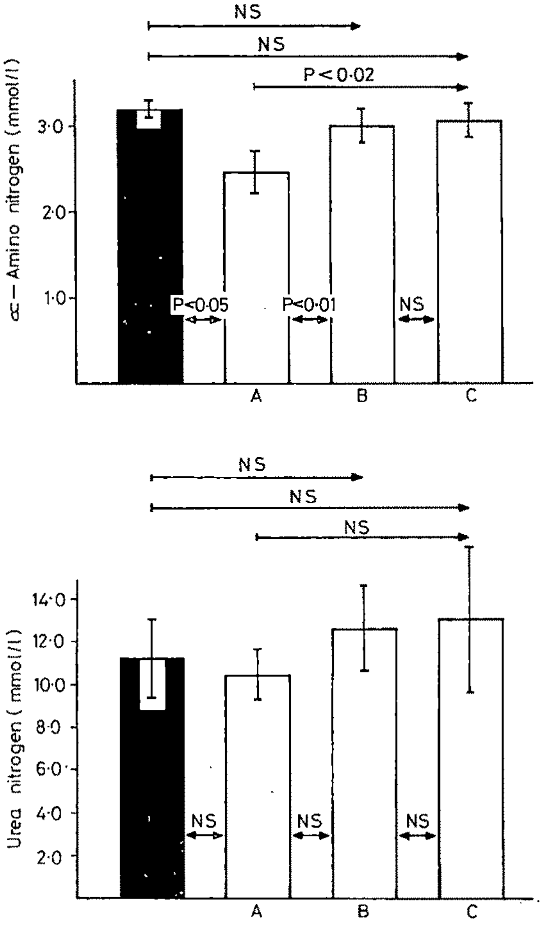

Fig. 2 *Plasma α-amino-nitrogen and urea nitrogen during infusion of* (*A*) *10% glucose,* (*B*) *10% glucose + 2.7% amino-acid, and* (*C*) *10% glucose + 2.7% amino-acid + 10% lipid.*

Unfortunately only 2 of the 6 infants in whom there were changes in the plasma concentration of 17 different amino-acids were tested before parenteral nutrition. However, from previous observations (Rubecz *et al.*, 1974) we know that glucose infusion causes a pronounced fall in most individual amino-acids, and the same response of the plasma α-amino-nitrogen was seen in our study. The hypoamino-acidaemic effect of 10% glucose is also evident if the combined fasting concentration of the 17 amino-acids obtained in the 2 infants (2673 µmol/l) is compared with that obtained by the end of the 10% glucose period in 6 infants (1559 µmol/l). The

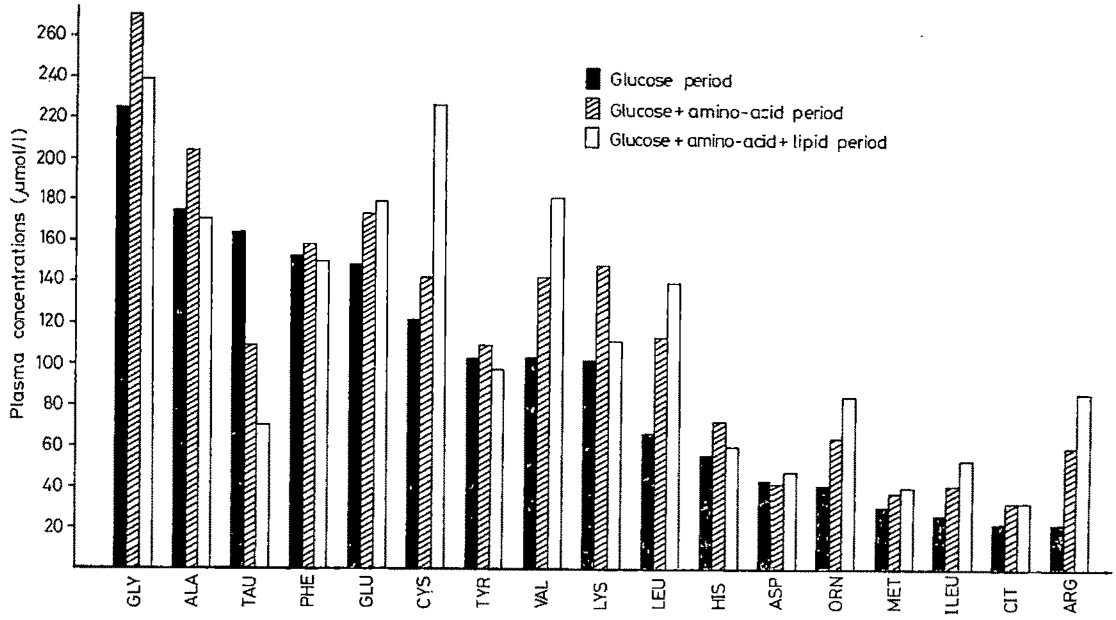

Fig. 3 *Concentrations of individual plasma amino-acids during the three intravenous nutrition regimens.*

responses of the individual amino-acids in the second and third 12-hour periods of intravenous nutrition are shown in Fig. 3. Owing to the small number of infants in whom each of the 17 amino-acids could be followed throughout the three infusion periods, statistical analysis was not made, but 13 amino-acids clearly increased their plasma concentrations when glucose was supplemented with amino-acid solution. The rise of phenylalanine, tyrosine, and asparagine was negligible. It is interesting that one amino-acid, taurine, responded to the addition of the amino-acid by a pronounced fall.

By the end of the third infusion period, when fat was added to the glucose and amino-acid mixture, a further rise was observed in the levels of 8 amino-acids (glutamine, cystine, valine, leucine, ornithine, methionine, isoleucine, and arginine), with no change or fall in the concentration of glycine, alanine, tyrosine, lysine, histidine, asparagine, citrulline, and phenylalanine. Among those amino-acids whose concentration decreased in response to lipid, in none did the concentration fall below that at the end of the first infusion period. Taurine, however, showed a further pronounced fall when glucose and amino-acid was supplemented with lipid.

Insulin and growth hormone response. The mean responses of plasma insulin and growth hormone (GH) are shown in Table 2. By the end of the 10% glucose period the mean plasma level had increased. The addition of amino-acid mixture to the infusate caused a further increase in the mean level of both hormones. By the end of the third period plasma insulin and GH mean levels were both lower.

It should be noted that the magnitude and the time course of individual insulin response (Fig. 4) showed

much variation. The changes in GH were more uniform. The definite increase elicited by 10% glucose was followed by a further pronounced increase in response to the combined infusion of glucose and amino-acids, when addition of lipid was associated with a pronounced fall.

Discussion

It has been shown that the basal metabolic rate of small infants and the total daily heat production is considerably less (Mestyán *et al.*, 1968; Rubecz and Mestyán, 1975) than that predicted by Gordon and Levine (1936). The three levels of caloric intake (lower, equal, and higher than the basal requirement) represented by the three infusion periods were chosen to take account of this newer information.

Changes in blood glucose and FFA. As in our previous observations (Rubecz *et al.*, 1974) hypertonic glucose infusion caused a rise in blood glucose and a fall in plasma FFA. The fall in FFA became more pronounced by addition of the amino-acids to 10% glucose, but blood glucose was much lower. As expected, the addition of fat emulsion led to a substantial rise in plasma FFA, blood glucose remaining unchanged.

Responses in plasma amino-acids and urea level. The hypoaminoacidaemia observed by the end of the 10% glucose period is in accordance with the known interrelationship between carbohydrate and amino-acid metabolism (Munro and Thomson, 1953). The removal of amino-acids from the plasma as shown by the fall in α-amino-nitrogen content was significant. It is noteworthy that the rise in plasma α-amino-nitrogen after amino-acid supplementation did not exceed the fasting level. This confirms our previous finding (Rubecz *et al.*, 1974) that administration of hypertonic glucose is an effective means of avoiding hyperaminoacidaemia, a potentially dangerous consequence of infusing amino-acid mixtures. It is also significant that the normal total plasma amino-acid level was maintained during the third 12-hour period when lipid was infused in addition to the glucose and amino-acid solution.

Supplementation with amino-acid mixture increased the plasma concentrations of most individual amino-acids. The increment was variable and seemed to reflect the composition of the amino-acid solution infused. Taurine was the only amino-acid where plasma level fell throughout the infusion periods. The infusion of lipid in addition to glucose and amino-acids altered the plasma amino-acid pattern appreciably.

The fact that blood urea was practically unchanged indicated that the amount of amino-acids infused did not cause a rate of urea production which exceeded the renal excreting capacity. In view of the possibly increased amino-acid transport to tissues due to stimulated insulin secretion (Kipnis and Noall, 1958) it appears reasonable to assume that the anabolic use of amino-acids was also improved when the caloric input, and hence the amino-acid load, did not exceed the maintenance energy expenditure.

Changes in plasma insulin concentration. The magnitude and time course of the individual changes in plasma insulin were found to be variable. This particularly applied to the glucose period when a marked or a moderate response was observed or sometimes none. This is consistent with reports which point out that the insulin response to a glucose load in either normally grown or growth-retarded low birthweight infants is generally poor, particularly within the first 48 hours of life (Baird and Farquhar, 1962; Milner and Hales, 1965; Grasso *et al.*, 1968; Gentz *et al.*, 1969). The change of plasma insulin after supplementation of glucose with amino-acids was also found to be variable: it either elicited a small rise in infants in whom glucose was ineffective, or maintained the moderate increase caused by glucose infusion. In two infants it even abolished the glucose-stimulated insulin secretion. These observations are in accordance with the observations of Pildes and Wong (1973) and with our previous study (Rubecz *et al.*, 1974) in which administering amino-acids in addition to glucose failed to enhance insulin secretion. The low birthweight, immaturity, and pathological conditions of infants included in the previous and present studies may be a relevant factor in explaining the lack of synergism between glucose and amino-acids, and the inconsistent pattern of insulin response.

Although direct evidence for an effect of plasma FFA on insulin secretion in man is lacking, FFA have been shown to stimulate insulin secretion in the dog (Crespin *et al.*, 1969). In the present investigations lipid did not seem to modify consistently the plasma insulin content, which either remained unchanged or fell to the fasting level. In only one infant was a further appreciable increase observed. Asch *et al.* (1975) reported a somewhat higher (but nonsignificant) insulin level in infants in response to a 12% glucose +2·5% amino-acid and 10% soybean oil emulsion parenteral nutrition regimen, compared with the infusion of a mixture of 12% glucose and 2·5% amino-acid solution.

Changes in plasma growth hormone concentration. Unlike the changes in plasma insulin, the response of GH was more uniform. In all infants but one, the response induced by 10% glucose was further increased by the supplementation with amino-acids. It is well known that in newborn infants glucose induces GH release, and amino-acids—such as arginine—are also potent stimuli (Stubbe and Wolf, 1970; Le Dune, 1972; Stubbe *et al.*, 1973). It is interesting that further supplementation with lipid depressed GH level in most infants, in some it completely abolished the response elicited by glucose and glucose amino-acids. In adults (Blackard *et al.*, 1971), and in rhesus monkeys (Blackard *et al.*, 1969), the administration of corn oil emulsion and heparin suppressed insulin and arginine-induced GH secretion, and it was suggested that this effect might have been due to the FFA component. It is conceivable that in the present study the pronounced rise in plasma FFA concentration in response to lipid supplementation was mainly responsible for the inhibition of stimulated GH secretion.

Besides the changes in hormonal status the administration of lipid was also associated with alterations in the plasma aminogram: the concentrations of a number of amino-acids increased. As GH is known to augment the amino-acid uptake of the tissues (Snipes, 1968) it is reasonable to assume that the raised levels of some amino-acids in response to lipid was the result of suppression of GH secretion.

Conclusions

In view of recent estimates of the maintenance caloric need of low birthweight infants kept at a neutral temperature (Mestyán *et al.*, 1968; Rubecz and Mestyán, 1975) the calories infused throughout the third 12-hour period were, in all probability, high enough to cover maintenance energy expenditure and low enough to avoid undesirable metabolic complications. The distribution of calories of the infusate appears also properly balanced as far as the plasma metabolic profile is concerned. The lack of pronounced biochemical distortions indicate that the pattern of substrate use is also less unphysiological than might be expected with a caloric input much exceeding heat production.

It is time to re-evaluate the energy side of parenteral feeding in low birthweight infants. An individual approach to the estimation of the caloric need for maintenance must be adopted. The components of total heat production (basal metabolic rate, specific dynamic action, activity, thermoregulatory heat production) may vary considerably according to maturity, postnatal age, feeding, and thermal conditions. These factors require individual assessment if the caloric requirement of an individual infant is to be determined.

It is also important to know whether parenteral feeding is to cover maintenance substrate and energy requirements, or is to provide additional calories for growth. In view of the usual absence of growth in low birthweight neonates during the first 10 days of life, it appears unnecessary to increase the caloric input above the maintenance requirement, otherwise most of the extra calories and substrates would probably be rapidly oxidised rather than incorporated in the body tissues.

Mycoplasma pneumoniae infection

A follow-up study of 50 children with respiratory illness

JACQUELINE Y. Q. MOK, PETER R. WAUGH, AND HAMISH SIMPSON

The Royal Hospital for Sick Children, Edinburgh, and
Department of Child Life and Health, University of Edinburgh

SUMMARY Fifty children with a previous history of *Mycoplasma pneumoniae* respiratory tract infection were assessed clinically, and pulmonary function tests carried out after an interval ranging from 1½ to 9½ years (median 2½). 23 suffered from recurrent wheezy bronchitis or asthma, and in 5 the index illness appeared to precipitate the wheezing tendency. All were symptom-free when respiratory function tests were performed. Simple tests of ventilatory function (PEFR, FEV, and FVC) were within normal limits. Increased bronchial reactivity after exercise (a fall in PEFR $>15\%$ resting value) was demonstrated only in children known to have asthma. Maximum expiratory flow rates in air at 50% of vital capacity ($\dot{V}\,max_{50}$) were within the normal range in all patients with the exception of two. The response in flow rate at 50% of vital capacity after inhalation of an 80% helium and 20% oxygen mixture ($\Delta\dot{V}\,max_{50}$) was reduced ($P<0{\cdot}001$) in asymptomatic patients with a history of *M. pneumoniae* respiratory infection, when compared with normal data from 48 healthy schoolchildren without a background of significant respiratory illnesses. These findings indicate impairment of small airways function, even in totally symptom-free children in the study group.

The clinical manifestations of *Mycoplasma pneumoniae* infection in children have been extensively reviewed (Baernstein *et al.*, 1965; Glezen *et al.*, 1967; Fernald *et al.*, 1975; Stevens *et al.*, 1978; Mok *et al.*, 1979). The clinical course of infections caused by this organism is usually self-limiting whether or not the child has had an effective antibiotic. Studies of pulmonary function after *M. pneumoniae* infection in adults show functional abnormalities both in the acute stage (Dierckx and Gillard, 1976) and after clinical and radiological recovery (Berven, 1962). In children with respiratory symptoms studies have been confined to the acute phase of illness (Kjellman, 1976), and we have been unable to find information on pulmonary function status after clinical and radiological recovery. We report here our findings in 50 children with proved *M. pneumoniae* infection studied 1½ to 9½ years (median 2½) after their index respiratory illnesses.

Patients and methods

Patients. The names of all children admitted to the Royal Hospital for Sick Children in Edinburgh with *M. pneumoniae* infection during the period from January 1968 to December 1975 were obtained from the records of the Regional Virus Laboratory in Edinburgh. The case records of 103 children were then traced and analysed. 87 with respiratory illnesses were chosen for further follow-up study. Letters were sent to their parents requesting cooperation. Of 57 replies received, 5 declined and 2 did not attend for study. We did not attempt to trace the remaining 30 patients.

Fifty children (20 girls and 30 boys) aged 0·4 to 11·3 years (median 4) at the time of the index illness were studied after an interval of 1½ to 9½ years (median 2½). Chest *x*-rays obtained during the acute phase of illness showed pneumonic consolidation in 19 (16 involving one lobe and 3 more than one lobe), patchy infiltration in 19 (unilateral in 8 and bilateral in 11), and hyperinflation in 2. In the 10 remaining patients with normal chest *x*-rays, cough was the main presenting symptom.

Plan of investigation. A clinical questionnaire on each child was completed by one of us (J.Y.Q.M.). Any history of a previous respiratory illness (acute bronchiolitis, whooping cough, pneumonia, measles or chickenpox with chest involvement, or tuberculosis) and/or ongoing symptoms (cough, wheeze, breathlessness, or sputum production) before or after the index illness was noted. Each child was then examined and respiratory function tests carried out in those old enough to co-operate.

With the patient standing, peak expiratory flow rate (PEFR) was measured using the Wright's peak flow meter (Wright and McKerrow, 1959). The best of 3 attempts was accepted. Forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) were measured using the Vitalograph spirometer, and the FEV_1/FVC ratio calculated.

Maximum expiratory flow volume (MEFV) curves were obtained breathing air followed by an 80% He/20% O_2 mixture. Each child was seated and breathed quietly through a mouthpiece and an attached Lloyd valve. The subject exhaled to residual volume and then performed 3 vital capacities (VC), first breathing air and then the He/O_2 mixture. During the 3rd VC manoeuvre, the child expired forcibly and completely into a 'bag and box' arrangement. Displaced air passed through a flow meter (Mercury Electronics, Scotland Ltd, Glasgow). A linear relationship between flow and output voltage was achieved electronically (Tau Electronics Ltd, Edinburgh). Linearity was checked each week and remained remarkably constant. Volume was obtained from the linearised flow signal using an integrator (Tau Electronics Ltd, Edinburgh). The pneumotachygraph was calibrated for air flow using a rotameter (GEC-Elliott, Process Instruments Ltd, Croydon). A volume calibration was carried out before each study using a 1-litre (BTPS) syringe. An identical volume signal was obtained for flow rates up to 500 l/min. MEFV curves were obtained by displaying flow against volume on the x-y coordinates of a storage oscilloscope (Tektronix Inc., Beaverton, Oregon). An electronic time marker indicated FEV_1. The curves were then photographed and analysed. Previous studies on normal children (H. Simpson, 1977, unpublished observations) had shown that observed differences between curves were independent of the order in which gases were inspired. Curves were compared when the vital capacity breathing He and O_2 was within 5% of that obtained in air. The variables measured were FEV_1, FVC, maximum expiratory flow rates at 50% of VC ($\dot{V}\ max_{50}$) and 25% of VC ($\dot{V}\ max_{25}$) for both the air and He/O_2 curves. The change in flow rate after inhalation of the He/O_2 mixture was measured at both 50 and 25% of VC ($\Delta\ \dot{V}\ max_{50}$ and $\Delta\ \dot{V}\ max_{25}$ respectively).

Patients with a resting PEFR >70% of predicted for height were exercised on a treadmill (Quinton Instruments, Seattle, Washington) for 6 minutes at a speed of 5 km/h at a gradient of 20%. The heart rate was measured after exercise and in each case was at least 160/min. PEFR was measured before exercise, then immediately and at 2, 5, 10, 15, and 30 minutes after cessation of exercise. The percentage fall in PEFR from the resting value was then calculated (fall in PEFR/resting PEFR) × 100.

Results

Clinical. An analysis of case records and clinical questionnaires showed a history of bronchiolitis,

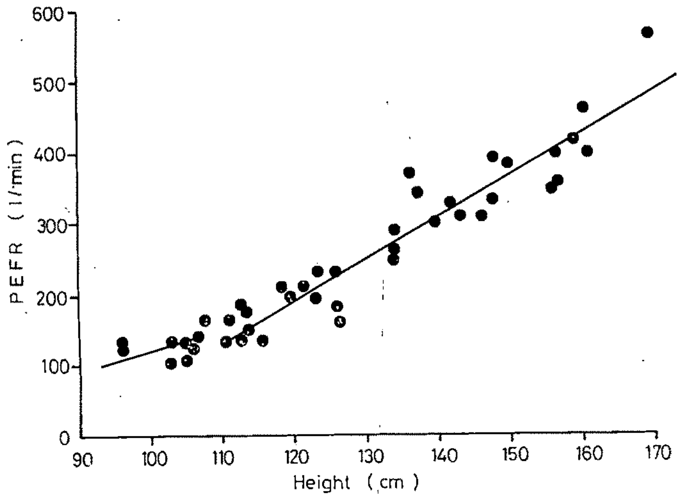

Fig. 1 *Peak expiratory flow rate in 43 children with previous* M. pneumoniae *respiratory infection.*

pneumonia, whooping cough, measles, or chickenpox with chest involvement antedating the mycoplasma illness in 17 children. After recovery, 8 remained symptom-free. Nine had recurrent wheeziness, 8 of them since infancy. 33 children had no specific antecedent illnesses. 19 were symptom-free and 14 had a wheezing tendency which predated the index illness. Six children developed persistent cough or wheeze for the first time after the mycoplasma illness. Five of these (all with recurrent wheeze) had a strong personal or family history of atopic disorders (eczema, food allergy, allergic rhinitis).

On examination 4 children were <10th centile for height and weight and 17 had mild to moderate degree of chest deformity. All patients were symptom-free and had no clinical signs of airways obstruction when respiratory function tests were performed.

Respiratory function tests. Fig. 1 gives the results of PEFR in relation to the normal data of Polgar and Promadhat (1971) and Milner and Ingram (1970). PEFR exceeded 70% of the predicted for height in all but one child. The results of FEV_1 and FVC were within normal limits, compared with the data of Polgar and Promadhat (1971). The FEV_1/FVC ratio expressed as a percentage was 85·1 (±7·8). When patients with wheezy bronchitis or asthma were excluded this ratio was 86·7 (±8·0).

MEFV curves breathing air and then a He/O_2 mixture were obtained in 28 children. 18 had been symptom-free both before and after their index illnesses, 4 had occasional mild wheeze, and 6 were known asthmatics. The results were analysed and compared with 'normal' values obtained in 48 schoolchildren of similar heights and age range but without antecedent lower respiratory tract infections or wheezing tendency. No difference was seen with respect to FEV_1 and FVC between the study and control groups.

Figs 2 and 3 show that in all but 2 patients, the results obtained for $\dot{V}\,\mathrm{max}_{50}$ and $\dot{V}\,\mathrm{max}_{25}$ were within or above the normal range for controls. Figs 4 and 5 show the results for $\Delta\dot{V}\,\mathrm{max}_{50}$ in the control and non-asthmatic patients within the study groups. $\Delta\dot{V}\,\mathrm{max}_{50}$ varies widely even in normal healthy children but in most cases exceeds 20 l/min. Table 1 gives the mean values ±SD for $\Delta\dot{V}\,\mathrm{max}_{50}$ and $\Delta\dot{V}\,\mathrm{max}_{25}$ in our controls and the 22 patients studied who did not have asthma. The $\Delta\dot{V}\,\mathrm{max}_{50}$ of 12·6 ± 13·7 l/min in our study group differed significantly ($P<0{\cdot}001$) from 24·4 ± 20·8 l/min in our controls. The 22 patients included 4 in whom chest *x*-rays were normal during their index illnesses. The values for $\Delta\dot{V}\,\mathrm{max}_{50}$ in these patients were 5, 10, 10, and 25 l/min. When our results were reanalysed, excluding data from these patients, significance remained unaltered. There was no relation between $\Delta\dot{V}\,\mathrm{max}_{50}$ or $\Delta\dot{V}\,\mathrm{max}_{25}$ and height in either the control or study group.

Table 2 *Exercise test in 34 children*

Ongoing symptoms (%)	*Fall in PEFR*		
	<10	*10–15*	*>15*
None	16	5	0
Wheeze/cough	4	1	8
Total	20	6	8

Table 2 summarises the results of the exercise study obtained in 34 patients. Of the remaining 16, 14 were preschool children who could not be persuaded to perform the test, one had a PEFR less than 70% of predicted, and another withdrew from the test after 2 minutes of exercise. 20 children showed a normal response to exercise, namely a fall in PEFR in the postexercise period of <10% of the resting value (Silverman and Anderson, 1972). The 8 children with a fall in PEFR >15% of the pre-exercise value were known asthmatics in whom a wheezing tendency antedated their mycoplasma illnesses. One of the remaining 6 children with a fall in PEFR of between 10 and 15% after exercise had only minor symptoms.

Discussion

Our results show that after clinical and radiological recovery from *M. pneumoniae* respiratory tract infection in children, routine tests of ventilatory function do not show abnormality, although the series included 10 children with wheezy bronchitis and 13 with asthma in remission at the time of study. Kjellman (1976) reported a decrease in FEV_1 and FVC in children with *M. pneumoniae* pneumonia during the acute phase of their illness, which returned to normal within a week. However, distribution of ventilation, assessed by ^{133}Xe radiospirometry, remained abnormal for a longer period and in one of 9 children persisted several months later.

Mycoplasma chest infection may be associated with wheeze in otherwise normal children, or may precipitate wheeze in those with a wheezing tendency (Berkovich *et al.*, 1970). Our series had a high proportion of children with wheezy bronchitis or asthma, including 5 patients who developed wheeze for the first time after the index illness. It seems likely that they would have developed asthma, for each had a strong background history of atopy.

The importance of exercise studies in showing increased bronchial reactivity and thus an asthmatic tendency has been demonstrated both in normal and asthmatic children (Godfrey, 1974). Our patients who had a fall in PEFR after exercise $>15\%$ of the pre-exercise value were known to have asthma and had been shown previously to have reversible airways obstruction. Sims *et al.* (1978) demonstrated bronchial hyper-reactivity in children 8 years after recovery from respiratory syncytial virus bronchiolitis in infancy, but they were careful not to infer a cause and effect relationship, but rather suggested that an environmental factor (low socioeconomic status or parental smoking) was the most likely link between respiratory infection in infancy and subsequent respiratory symptoms. Three of our 34 patients who did the exercise test gave a history of bronchiolitis in infancy from which they had recovered without further symptoms. All showed a normal response to exercise. It seems therefore that abnormal bronchial reactivity in our present series was due to including children with coexistent asthma and was not the result of antecedent bronchiolitis or the index mycoplasma respiratory illness.

It is now apparent that considerable obstruction of peripheral airways of the lung may be present before routine tests of ventilatory function show any abnormality. As a result there has been a search for new tests of lung function which are simple and sensitive (Macklem, 1972). One such test is based on a comparison of MEFV curves with the subject breathing air followed by an 80% He/20% O_2 mixture (Dosman *et al.*, 1975). We have shown an impaired response to the inhalation of this mixture at 50% of VC in a group of asymptomatic non-asthmatic children with a history of *M. pneumoniae* chest infection. It might be argued that equilibration with helium was incomplete after 3 VC manoeuvres. However, Dosman *et al.* (1975) demonstrated in symptom-free adults with normal values for routine ventilatory function tests that 3 successive VC manoeuvres were adequate to ensure equilibration with helium. This method gave results comparable with those obtained by Despas *et al.* (1972). We assumed that this was also true in our patients. The response to breathing the He/O_2 mixture was also less than in controls at 25% of vital capacity but the difference was not significant (Table 1). Impairment of response is more likely to reflect events in peripheral airways the closer to residual volume that measurements are made. However, the methodological difficulty of measuring low flow rates accurately, especially changes in flow rate, increases greatly in this part of the flow-volume curve. This may explain, at least in part, the wide range of values for $\dot{V}\ \mathrm{max}_{25}$ breathing air in both control and index cases, and account for the $\triangle\ \dot{V}\ \mathrm{max}_{25}$ being less discriminating an index of small airways dysfunction than $\triangle\ \dot{V}\ \mathrm{max}_{50}$ in the present series.

Our control data were obtained from schoolchildren attending a state primary school which served a community with children from differing socioeconomic backgrounds. Our patients were similarly drawn from varied social backgrounds. A social bias in the selection of controls is unlikely, although no attempt was made to match precisely the study and control groups of children on this basis. In our analysis of MEFV curves (Table 1) we excluded children with a background history of asthma. Thus no patient in either group had significant respiratory symptoms. We conclude therefore that impairment of response in flow rate at 50% of VC to the He/O_2 mixture was due to preceding *M. pneumoniae* respiratory infection. It is not possible to say whether the impairment of function represents permanent residual lung damage or whether these children are at risk of chronic obstructive airways disease in later life.

We thank the Cystic Fibrosis Research Trust and the Lothian Health Board for generous financial support, and Mrs D. Tervit for secretarial assistance.

Normal children with large heads—benign familial megalencephaly

R. E. DAY AND W. H. SCHUTT

Bristol Royal Hospital for Sick Children

SUMMARY Fifteen normal children with large heads (circumference >0·5 cm above the 98th centile) were studied. CAT scans were performed to exclude hydrocephalus, and ventricular size was compared with that of hydrocephalic children. In 11 of the 13 families in which the parents' heads were measured, one parent (10 fathers and one mother) was found to have a large head, as had 6 of 17 siblings. Head circumference at birth was large in 7 of 10 babies and rate of head growth was excessive in 8 of 13. Skull *x*-ray showed suture diastasis in 7 infants. These families have a benign familial megalencephaly. It is important to recognise this so as to avoid unnecessary investigation and anxiety about normal children with large heads.

A large head—macrocephaly—may be due to hydrocephalus, megalencephaly, a space-occupying lesion, or a thick skull. A large brain—megalencephaly—is associated with some cerebral degenerative disorders, as well as with other conditions—for example neurofibromatosis and achondroplasia—which are usually recognised by associated physical stigmata. Isolated megalencephaly while described in some gifted individuals—for example Byron, Turgenev, Bismarck—is generally considered to be associated with fits and retardation (Laurence, 1964).

Nelson and Deutschberger (1970) related the IQ at 4 years to head circumference (HC) at one year in 9379 children. They found that those with HCs >0·5 cm above 98th centile had a slightly higher mean IQ than children with heads of average size. One family in which father and son had large heads, normal intelligence, and normal computerised axial tomography (CAT) was reported by Asch and Myers (1976). Four other normal male relatives also had large heads. DeMyer (1972) reported 18 children with large heads and normal ventricular size on pneumoencephalography (AEG), but only 5 of these were of normal stature and neurologically normal. One of these had normal relatives with large heads.

When considering whether children with large heads are normal or not it is important to exclude hydrocephalus; Laurence and Coates (1967) showed that some children with untreated hydrocephalus had average intelligence. CAT enables us to identify normal children with large heads who do not have hydrocephalus, so we studied the head growth, skull *x*-rays, CAT appearances, and head size of such children.

Method

Graphs (Nellhaus, 1968) were used to obtain standards for HC. Of 26 children who were investigated for large head size and found not to have hydrocephalus, 3 were mentally retarded and 8 had a HC only just above the 98th centile. Thus 15 children were investigated (14 CAT, 1 AEG) who fulfilled our criteria, having HCs >0·5 cm above the 98th centile and being of normal stature and developmentally and neurologically normal.

Results

Of the 15 children 11 were boys. The HC at birth was known for 10 of them and 7 were >98th centile (36·5 cm for girls, 37·5 cm for boys). Two of the children with large heads at birth were delivered with Kielland's forceps and a further child had a difficult normal delivery. The expected rate of head growth was calculated from the HC chart; in 8 children this was found to be faster than normal, 5 were growing at a normal rate, and 2 were not seen in the first 2 years of life. Four of the children had been noticed to be hypotonic in early life, one had a squint, and one speech delay.

Skull *x*-ray. All children had skull *x*-rays performed between one month and 5 years. These were examined

W. H. SCHUTT, consultant paediatrician

independently by two radiologists. Seven of the children were thought by both, and a further 4 by one, to show suture diastasis. Cranial capacity was estimated by the method of Gordon (1966) and was >95th centile in 14 cases and on the 95th centile in one. The volume related better to the HC than to the measurements of ventricular size on CAT. One child (Case 14) had a very thick dense skull vault with a low width/length ratio and a high height/width ratio.

CAT scan appearance. 14 of the 15 children had CAT scans. The ventricular size was measured in two ways. The bifrontal and bicaudate diameters of the frontal horn of the lateral ventricle were measured at the level of the basal ganglia (as described by Hahn and Rim, 1976) and compared with brain diameter at the same site to give a ratio (cerebroventricular index). The upper limit of normal in adults for the bifrontal ratio is 39·3% and for the bicaudate ratio 23·1%.

Cerebroventricular indices in the 13 normal children with large heads are shown in Fig 1 (group A) (ventricles too small to measure in one) and compared with 8 otherwise normal children whose HC was on the 98th centile (group B), and 12 children later treated for hydrocephalus (group C). Fig. 1 shows that the indices are within the normal adult range, apart from Case 10 (Fig. 2).

As the body of the lateral ventricles is often more dilated than the frontal horns, the area of the ventricles at the level of the above measurements and at the next higher cut was measured with a planimeter and compared with the area of the brain at the respective cut to give a ratio of ventricular to brain area at two levels. These area ratios are shown in Fig. 3. The measurements of the normal large-headed children are within the same range as those with heads on the 98th centile and, with one exception, do not overlap those with hydrocephalus. This child with hydrocephalus had relatively small

ventricles although he had marked dilatation of the subarachnoid space and evidence of raised intracranial pressure.

Thus the normal children with large heads, except Case 10, had ventricular measurements which came within the normal range.

Family head size (Table)

Parents. Of the 15 children with large heads, 11 (10 fathers and one mother) of the parents had heads >98th centile (males >58·5 cm, females >58 cm). Only 2 children had parents with head circumferences within the normal range. Three parents were not available to be measured, one child having been adopted.

In families where the history was negative, one child (Case 13) had had viral meningitis at age 5 months and the other (Case 14) had a somewhat thick skull. The HCs of parents of 11 children in the hydrocephalus group were all <98th centile.

Siblings. Of the 11 children who each had one parent with a large head, 9 had 17 siblings (11 boys and 6 girls). Six (4 boys, 2 girls) of these had HCs >0·5 cm above the 98th centile for age. Two siblings also had hydrocephalus, of whom one had gross ventricular dilatation and was stillborn. Necropsy showed widespread old and new haemorrhage of undetermined aetiology. The other child with hydrocephalus was a twin to one of the index cases; he had a normal HC at birth which rapidly increased, and at 9 weeks AEG showed a communicating hydrocephalus which was treated with a ventriculo-atrial shunt. Of the 2 children whose parents did not have large heads, one had 2 sisters with normal sized heads and the other had a sister whose head was not measured.

Second-degree relatives. Of the 11 parents with large heads, 6 had their own parents' heads measured, and in 3 the grandfather's head and in one the grandmother's head was large. Four of the parents with large heads had siblings, in 2 the HC was normal, in one it was large, and one was not measured.

The following case illustrates some of these points.

Case report

A baby boy (Case 6) born at 39 weeks' gestation by Kielland's forceps for deep transverse arrest. Birthweight 4·25 kg, length 57 cm, HC 39·5 cm. He was followed up from birth and investigated at 9 months when HC was diverging (Fig. 4) and skull *x*-ray (Fig. 5) showed suture diastasis, skull volume 1390 ml (normal 925–1050). CAT scan (Fig. 6) showed bifrontal ratio 35·5, bicaudate ratio 16·6, lower ventricular area 9·0, and upper ventricular area 12·6. At 18 months the child is walking and saying several words, and development appears normal. Fig. 7 shows the family tree. Father (HC 61 cm), the elder brother (57 cm at 3 years), paternal uncle (60·2 cm), and grandmother (60·4 cm), all have large heads. The grandmother said she never seemed able to find hats to fit her.

Discussion

All the 15 normal children with large heads had ventricular measurements on CAT scan which were within the normal range, except Case 10 in whom lateral ventricular measurements on low cuts (2A) were high (although well below most hydrocephalic babies). However measurement of the lateral ventricular area by planimetry was nearer the mean for the large-headed children. Nellhaus (1972) measured ventricular size by AEG and carotid angiography in 5 children with ‘benign idiopathic megalencephaly’ and found that the ventricles were in proportion with the cerebral mantle. Harwood-Nash (1977) stated that the CAT appearance of megalencephaly was that of normal or mildly dilated ventricles. Absolute measurements of ventricular size may be misleadingly high and comparison with brain size in a ratio, as done here, is more meaningful. A surprising finding in our series was of suture diastasis in 7 of the skull *x*-rays. This supports the view of Schönenberg (1973) that mild suture diastasis may not be an indication of raised intracranial pressure in young children. Conversely, he found that 12 of 39 infants with proved hydrocephalus had normal sutures.

The HC at birth was large in 7 of 10 babies. This may lead to difficulty during labour and delivery, and result in cerebral damage (Lorber and Bhat, 1974) with secondary mental retardation or neurological abnormality. Rate of head growth was increased in 8 of 13 children in whom it was measured giving the appearance of divergence from the centile lines. This was also seen in 2 of DeMyer’s (1972) tall children with large heads.

The finding that 11 of these children each had one parent with a large head and that 6 of 17 siblings also had large heads supports the suggestion of an autosomal dominant pattern of inheritance. The family described by Asch and Myers (1976) had 6 members in three generations with macrocephaly (all male). The family described by DeMyer (1972) had 4 confirmed and a further 4 suspected members with megalencephaly (4 female, 4 male) in three generations. Platt and Nash (1972) reported 4 normal children each having one parent with a large head but they did not give details. In our series there is a predominance of males 27:6 and the affected members in the family described by Asch and Myers (1976) were all males.

In two of our families one member had hydrocephalus. In one there was evidence of haemorrhage. In the other there was a communicating hydrocephalus. Schreier *et al.* (1974) described a family in which 2 members had hydrocephalus and 10 were normal with large heads. Three of these were investigated by echoencephalography which showed ventricles of normal size in one and at the upper limit of normal in two.

Thus 11 of our children have a benign familial megalencephaly which appears to be more common in males. The HC may or may not be large at birth and rate of growth may be excessive. Some of the children were hypotonic as infants but development was generally normal. Skull *x*-ray may show mild suture diastasis. CAT scan will usually clearly distinguish these children from those with hydrocephalus, although the ventricles may be at the upper limit of normal size.

It is concluded that in the absence of evidence of raised intracranial pressure or factors which might predispose to hydrocephalus or intracranial space-occupying lesion, the finding of a large head in an otherwise normal child should lead to the measurement of both parents' HC and, if one parent's head is large, the child should be observed rather than having further investigations, although CAT would reassure both doctors and parents.

We thank Dr J. L. G. Thomson and Dr I. R. S. Gordon for assistance.

Four families with immunodeficiency and chromosome abnormalities

D. C. A. CANDY, A. R. HAYWARD, D. T. HUGHES, L. LAYWARD, AND J. F. SOOTHILL

Departments of Immunology, Child Health, and Histopathology, Institute of Child Health, and The Hospital for Sick Children, London

SUMMARY Six children, with severe deficiency of some or all of the immunoglobulins and minor somatic abnormalities, had chromosomal abnormalities: (1) 45,XY,t(13q/18q), (2) 46,XY,21ps+, (3) two brothers 46,XY (inv. 7), (4) 45,X,t(11p/10p)/46X,iXq,t(11p/10p) and, (5) in addendum, 45,XX,−18; 46,XX, r18. The chromosome abnormalities were detected in B- as well as T-lymphocytes (as evidenced by using both PHA- and PWM-stimulated cultures) in all probands, but one was mosaic in PHA culture, although all his PWM-stimulated cells were abnormal. Chromosomal variants were also detected in relatives of three and immunodeficiency in relatives of two.

Only two firm associations between immunodeficiency and autosomal chromosome abnormality in phytohaemagglutinin (PHA) stimulated T-lymphocytes are recognised. Some patients with ataxia telangiectasia show general chromosome instability with many spontaneous breaks (especially of chromosome 14 and other D-group chromosomes) (Nelson *et al.*, 1975; Oxford *et al.*, 1975). IgA deficiency is sometimes associated with chromosome 18 abnormalities—deletions of short and long arm (Feingold *et al.*, 1969; Faed *et al.*, 1972), ring forms (Finley *et al.*, 1968), and large chromosomes (Yanagisawa, 1972). There are also reports of immunodeficient patients with other chromosomal abnormalities (Jacobs *et al.*, 1968; Kretschmer *et al.*, 1968; Calvani *et al.*, 1976), especially of the D-group. We studied the chromosomes in four immunodeficient children who had unusual facies; each had an abnormality.

As the immunodeficiency was of antibody we studied the chromosomes not only in PHA-stimulated lymphocytes (predominantly T-lymphocytes), but also in pokeweed mitogen- (PWM) stimulated lymphocytes (which include B-lymphocytes).

Methods

Immunoglobulins were measured by radial diffusion (Fahey and McKelvey, 1965). Lymphocyte thymidine uptake after PHA stimulus, E-rosette count, and surface immunofluorescence were by the method of Espanol *et al.* (1974). Chromosomal analysis of PHA-stimulated lymphocytes after colcemid treatment was by the method of Hungerford (1965).

For chromosomal analysis 0·05 ml PWM (Gibco, New York) was added to 5 ml cultures (Wybran *et al.*, 1973).

T- and B-enriched preparations of lymphocytes were prepared by rosetting techniques from Case 1 and a healthy donor, cocultured with PWM, and tested for cytoplasmic immunofluorescence for immunoglobulin (Hayward and Lawton, 1977).

Buccal smears for X-chromatin studies were prepared by a modification of the method of Klinger and Ludwig (1957). Hydrolysis in 1 mol/l HCL for 8 minutes was followed by staining for 10 minutes in 2% aqueous toluidine blue.

Family 1. Case 1, a boy, was investigated soon after birth because his maternal uncle had had life-long immunoglobulin deficiency (he died before the proband's birth). At birth Case 1 had limb swelling, deformed toe nails, spindle shaped fingers, microcephaly, and an unusual facies with fullness over the maxillary and mandibular bones. Immunoglobulin deficiency was found (see below) and replacement treatment was started, although he had had no obvious infection. At 15 months he developed convulsions, up to five a day. Several members of his father's family had had convulsions. Neutropenia was noted once. Levels of serum IgG, IgA, and IgM have been persistently very low. Lymphocyte count was normal with normal E-rosette count, and a high percentage positive for surface immunoglobulin immunofluorescence (Table). Chromosome analysis of PHA-stimulated cells showed a normal/translocation mosaic; 3 of 10 cells studied were normal;

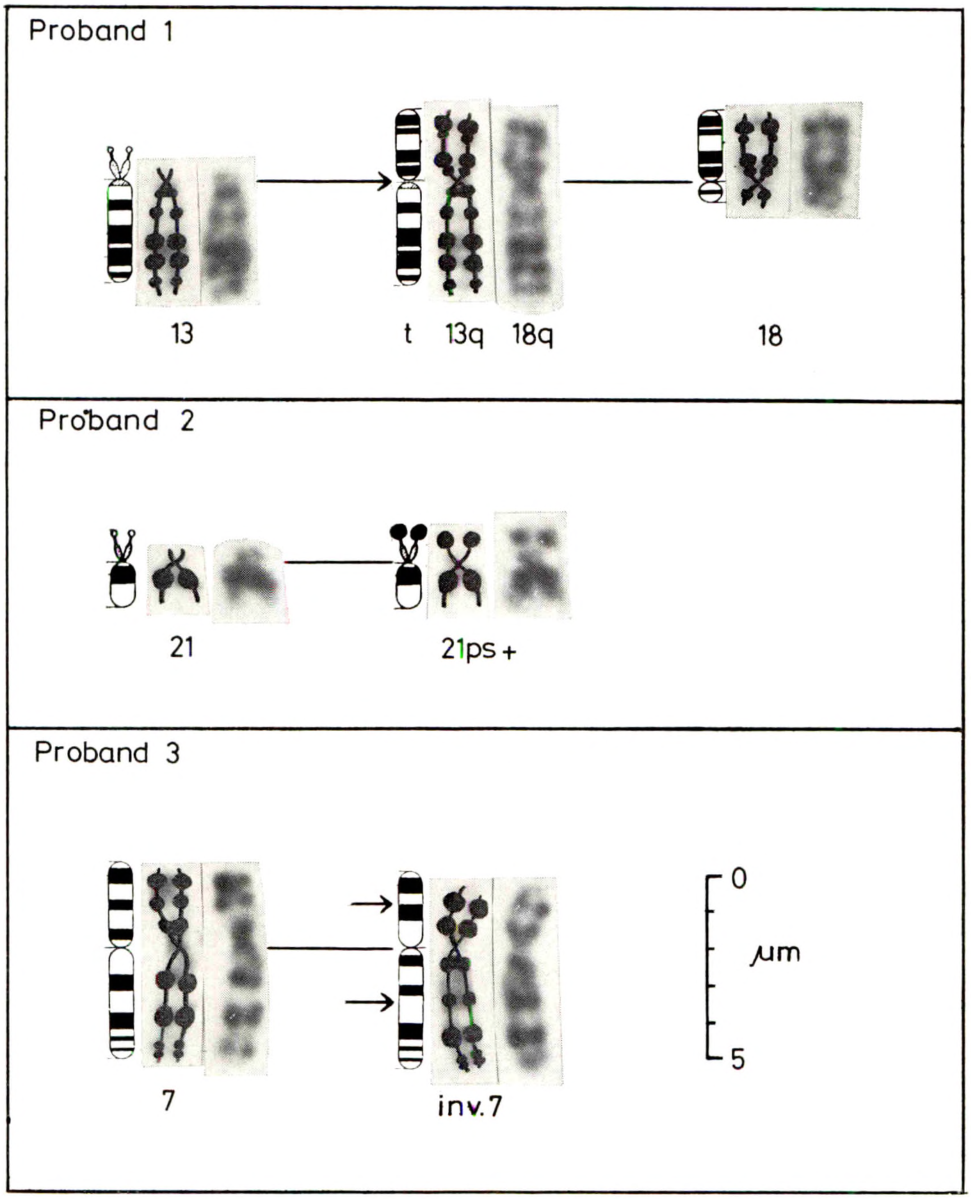

Fig. 1 (scale in microns). *Anomalous chromosome pairs from probands 1, 2, and 3. Photomicrographs of the normal and abnormal member of each affected chromosome pair are shown, in each patient, together with a drawing and the standard international diagram of the banding pattern (Paris Conference, 1972). Translocated chromosome in proband 1 (a mosaic) was formed by fusion of chromosomes 13 and 18, after loss of their short arms by breakage at the centromere (arrowed). Proband 2 has large satellites on chromosome 21. In proband 3, the arrows pointing to the inverted chromosome 7 (inv. 7) indicate the apparent breakage points at which the order of the bands has been reversed.*

Table *Immunological data on patients with immunoglobulin deficiency and chromosomal abnormalities. Lymphocyte PHA response is expressed in maximum DPM/0·01 ml whole blood. Lymphocyte forming rosettes with sheep red cells (E–RFC) and with surface immunoglobulin (SIg^+) are expressed as %*

	Father	Adult					174	149	128

in the remainder the long arm of an 18 was translocated on to the long arm of a 13; both the short arms were missing (Fig. 1). In PWM-stimulated cultures all 30 cells studied showed the translocation.

T- and B-enriched preparations from Case 1 and a healthy donor were co-cultured in different combinations and, after PWM stimulus, tested for cytoplasmic immunofluorescence for immunoglobulin; donor B-cells were positive whether cultured with autologous T-cells (6·5 × 10^4/well) or T-cells from proband 1 (9·3 × 10^4/well) but no positive cells were seen (<0·05 × 10^4/well) when B-cells from the Case 1 were cultured with either autologous or female donor T-cells.

His father had normal chromosomes in all PHA-stimulated cells, but count of E-rosette-forming cells was low (one study only, Table, Fig. 2). The immunological tests on his mother were normal, but the one cytogenetic study made suggests that she is mosaic, as 2 of 20 cells had an extra C-group chromosome. The uncle had had IgG and IgA deficiency with normal levels of serum IgM; no lymphocyte or chromosome studies were done.

Follow-up of Case 1 had shown retarded intellectual development, but convulsions have become less frequent without prophylactic treatment, and he has had no infections while on immunoglobulin injection.

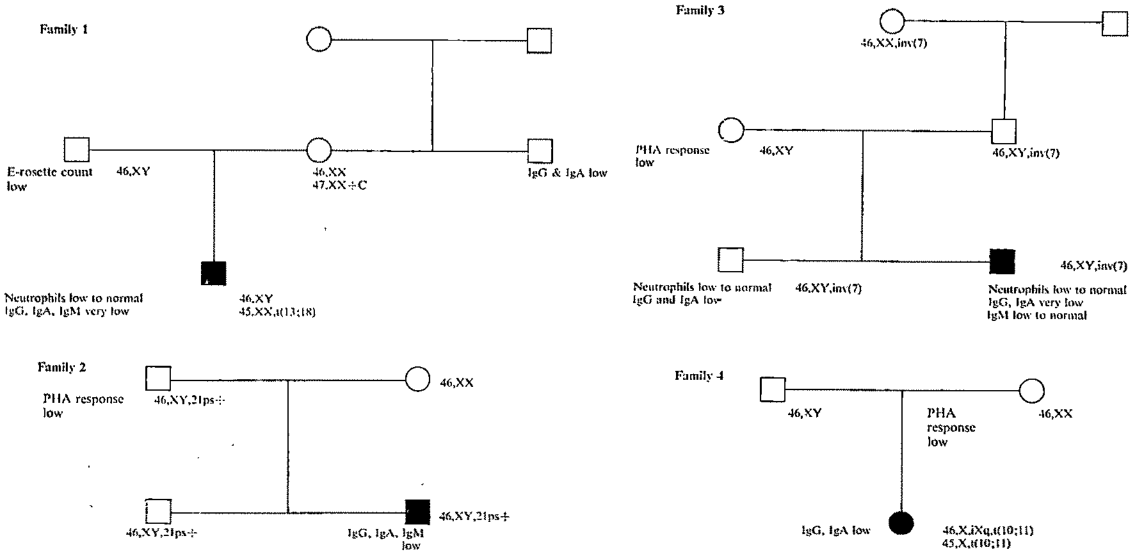

Fig. 2 *Family trees of 4 probands (● ■) with abnormalities of chromosomes and immunoglobulins. Abnormal immunological findings and results of chromosome analysis of PHA-stimulated lymphocyte cultures are given.*

Family 2. Case 2, a 9-month-old boy, was investigated for growth retardation, developmental delay, and repeated febrile illnesses with convulsions. He had an unusual facies, with a mongoloid slant to the eyes, hypertelorism, anteverted nares, and broad upper lip. He had hyperextensible joints and pigmented naevi on the occiput, thigh, and axilla. A cystogram showed bilateral ureteric reflux with parenchymal opacification of the left kidney. His head was asymmetric and a CAT scan showed cortical thinning, especially of the frontal lobes. There was evidence of respiratory and urinary infections.

Levels of serum IgG, IgA, and IgM were all very low. Salivary IgA and isohaemagglutinins were absent. Chromosome analysis of both PHA- and PWM-stimulated lymphocytes showed that all cells had a giant satellite on the short arm of chromosome 21 (Fig. 1). He has since had occasional mild respiratory infections while on prophylactic co-trimoxazole, and his convulsions are well controlled on sodium valproate; his psychomotor development is retarded.

His mother's immunological tests were normal, as were her chromosomes. Both his father and 4-year-old brother were well, but show the same chromosome aberration in all PHA- and PWM-stimulated cells. Although the brother is immunologically normal, his father has a low PHA response (Table).

Family 3. Case 3, a 4-month-old boy, was investigated for growth retardation and feeding difficulties. He had an unusual facies, with a low set left ear, anti-mongoloid slant to the eyes, and high arched palate. He was wasted and breathless. *Pneumocystis carinii* infection was diagnosed on lung aspiration and *Giardia lamblia* were found in the faeces. He had intermittent neutropenia and low levels of IgG and IgA. IgM was low but rose to normal. The anti-A isoagglutinin titre was 1/1. Salivary IgA was not detected. There was pericentric inversion of chromosome 7 on all cells on PHA and PWM cultures (this had previously been identified in PHA culture by Dr N. Gregson). He gained weight after treatment with immunoglobulin injections, co-trimoxazole, and metronidazole.

His mother had a low PHA response, but her other immunological tests and her chromosomes were normal. His paternal grandmother, father, and 4-year-old brother each showed the same chromosome abnormality. His father was well and immunologically normal. His brother had neutropenia on one occasion and has low levels of serum IgG and IgA. He was relatively well until recently apart from mild oral ulceration; this is now severe and immunoglobulin treatment has been started.

Family 4. Case 4, a 3-month-old girl, was investigated for growth retardation, prolonged hypocalcaemia (until 9 weeks old), and frequent infections: chronic oral and perineal candidiasis, chronic paronychia and pulp space infection, and septic arthritis of the hip. She had an unusual facies with micrognathia, high arched palate, and epicanthic folds. Pectus excavatum, widely spaced nipples, stridor, large umbilical hernia, hypotonia, anterior bowing of tibiae, and dystrophic nails were noted. Barium meal showed malrotation of the intestine.

Serum IgG and IgA were low and salivary IgA was not detected. E-rosette-forming cells, PHA response, and surface immunoglobulin immunofluorescence were normal. Of 20 cells studied, on PHA stimulus, 9 had a single X-chromosome (45, X) and 11 had an isochromosome for the long arms of X—that is she was a mosaic (Fig. 3). All lymphocytes showed an extra band on the short arm of chromosome 10, and a missing band from the short arm of chromosome 11. PHA and PWM cultures gave similar results. Of 300 buccal cells 16% showed Barr bodies (normal female range 15 to 30%); some were abnormally large. Her parent's chromosomes were normal; the mother's PHA response was low.

She has had no subsequent serious infections and serum calcium has remained normal without further treatment, but there is evidence of psychomotor retardation.

Discussion

The association of immunoglobulin deficiency with chromosome aberrations and abnormalities raises a number of possibilities. It may be coincidental as autosomal abnormalities are found in about 0·3% of newborn babies (Evans, 1977), and we are becoming increasingly aware that immunodeficiency is not rare. The occurrence of both in a single individual will be an occasional chance finding, but the detection by chance of a significant chromosomal abnormality or variation in all four probands we studied would be a very odd run of luck. It is possible that the structural and chromosomal abnormalities were causatively associated, and immunodeficiency, which brought them to our attention, was associated by chance.

The other possibilities for the association are that the chromosome abnormality may cause the immunodeficiency, or that the immunodeficiency may have led to abnormal handling of an intra- or extra-uterine viral infection by the child or the mother which might have caused the chromosome abnormality, or that both were caused by the same environmental factor, for instance by a virus infection (Soothill *et al.*, 1966). There is no history

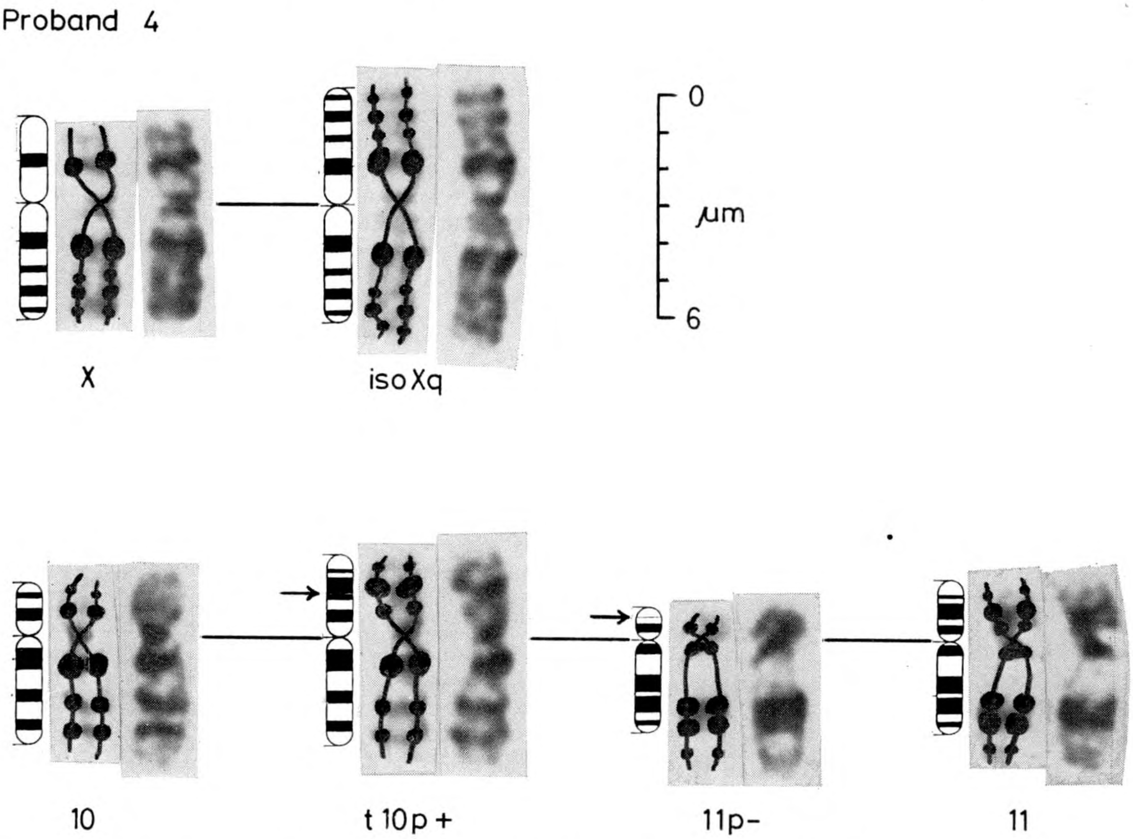

Fig. 3 (scale in microns). *Anomalous chromosome pairs from proband 4, presented in the same way as in Fig. 1. In addition to the normal X and isoXq (with its duplicated long arm), there are two abnormal autosomes which seem to be balanced for a translocation between chromosomes 10 and 11. Arrows indicate the apparent breakage points at which part of the short arm of an 11 broke off to become attached to the short arm of a 10.*

of overt viral infection during pregnancy in any of these families. It is very likely that the mechanism of the associations may be different in the different families. In families 2 and 3 it is more likely that they were coincidental as the chromosome abnormality was detected in an immunologically and structurally normal member of both families, but one cannot exclude the possibility that the abnormalities resulted from varying expression of the chromosome defect. The neutropenia in association with inversion of chromosome 7 in Case 3 is interesting in view of the report by Rowley (1973) of neutropenia with deletions of this chromosome. The known involvement of X-chromosome with immunoglobulin concentration (Butterworth *et al.*, 1967; Rhodes *et al.*, 1969) gives added significance to the finding in Case 4.

Although the family tree (Fig. 2) in family 1 suggests X-linkage, neither the normal IgM in the uncle, nor the normal number of lymphocytes with surface immunoglobulin in the child is consistent with X-linked agammaglobulinaemia, but there probably are other forms of X-linked immunodeficiency. Coincidental chromosomal abnormality with such an immunodeficiency must be considered, but there is evidence in favour of a causative relationship. The mosaicism of the T-lymphocytes (with apparently normal T-cell function, including that of co-operation) but the consistent chromosomal abnormality in the PWM-stimulated cultures, many of which would be B-lymphocytes which were functionally defective *in vitro* and *in vivo* would be an additional coincidence if the relationship were not causal.

The chromosomes affected in Case 1 have been previously associated with immunodeficiency—chromosome 18 with IgA deficiency (Feingold *et al.*, 1969; Faed *et al.*, 1972), and group- D chromosomes with IgM deficiency (Kretschmer *et al.*, 1968), and severe combined immunodeficiency (Calvani *et al.*, 1976). An association between swollen feet and chromosome 18 abnormality has been described (Vianna-Morgante *et al.*, 1976) without immunological data. Perhaps there was a generalised genetic predisposition to chromosome instability involving the C-group defect in the mother, the 13/18 in the child, and one which we can only guess at in the uncle, causing the immunodeficiency.

Cytogenetic study of both PHA- and PWM-stimulated cultures permits study of variation of mosaicism in different cell populations and organ-specific cell selection. Full interpretation of these relationships demands more data, but if such associations are found consistently, they may throw light on the chromosome distribution of genes which control immunity mechanisms, other than those already described.

Addendum

Since completing this paper we have observed a child with a ring 18-chromosome, who showed the somatic abnormalities and IgA deficiency similar to the child described by Finley *et al.* (1968). Our patient was mosaic for this abnormality (3 cells 45, XX, −18; 17 cells 46, XX, r 18).

We are grateful to Dr N. Gregson who first observed the chromosomal abnormalities in family 3, to Dr J. Stewart for help with studies on family 4, to Professor O. Wolff and Dr J. T. Harries under whose care the probands were admitted, and to Miss Doreen M. Farrington and Mrs Janette D. O'Connell for technical help.

Effects of physical training on hormonal responses to exercise in asthmatic children

SEPPO LEISTI, MATTS-JOHAN FINNILÄ, AND EIJA KIURU

Children's Hospital, University of Helsinki, Jorvi Hospital, Espoo, and Helsinki City Health Department, School Health Division

SUMMARY A 4-month period of physical training increased the physical working capacity of 16 asthmatic children (aged between 9·3 and 13·6 years) by a mean of 11%. The increase was greater in boys and was negatively correlated with pretraining capacity. Urinary excretion of adrenaline, measured during a submaximal exercise test, decreased during the training period; the decrease was correlated with the increase in working capacity. Before the training period, exercise induced an increase in the plasma cortisol level; no increase was evident after training. In contrast, the training did not affect the exercise-induced increase in the plasma growth hormone level.

Training programmes have been evaluated (Geubelle *et al.*, 1971; Vavra *et al.*, 1971; Fitch *et al.*, 1976) for improving the poor physical fitness of asthmatic children (Fowler and Gardner, 1963; Godfrey, 1974). The disturbing effect of exercise-induced bronchospasm (Jones *et al.*, 1962; Bierman *et al.*, 1975) can be avoided by swimming training (Fitch *et al.*, 1976) or by dividing the training into short bursts of activity (Strick, 1969). Exercise stimulates the secretion of several hormones (Felig and Wahren, 1975) and training may modify the responses (Hartley *et al.*, 1972a). Therefore, we set out to study whether the exercise-induced responses of adrenaline, cortisol, and growth hormone (GH) would change during a training programme for asthmatic children.

Subjects

Eight boys and 8 girls (see Table for clinical data) consented (with the approval of their parents) to participate in the exercise tests and the training programme. All the children had bronchial asthma diagnosed more than 4 years earlier. Five children had a history of exercise-induced asthma; all of them, and 2 others, used sodium chromoglycate inhalations. No oral corticosteroids were used, but 2 children took daily inhalations of beclomethasone. Sympathomimetic medication, if any, was stopped at least 10 days before the tests. No healthy child participated in the programme.

Training programme

During 4 winter months the children were offered a total of 31 sessions of training, on Mondays and Thursdays, after school in a gymnasium under the supervision of a physiotherapist. The children used a mean of 19 sessions, with a range of 12 to 28. The 60-min training session consisted of 10 min of warming up with light gymnastics, 5 min of breathing exercises, a 20-min period of four 1-min bursts of maximal activity (skipping-rope, fast jumping, stepping chair exercises, etc.), interrupted by rest and/or light gymnastics, 5 min of light exercises (rings, parallel bars, etc.), and 20 min of ball games or other sports (football, table tennis, relay race, etc.). In the rare case of exercise-induced bronchospasm the child took a break and did light breathing exercises until the attack ceased. No sympathomimetic drugs were needed.

Methods

The children were tested within 2 weeks before the beginning (pretraining test) and within 2 weeks after the end (post-training test) of the training programme. In the morning an indwelling venous cathether was introduced for collecting blood samples. Just before the test, the child urinated and a basal blood sample

was taken. Then samples were taken half-hourly for 2 hours, a 2-hour urine sample was collected, and tetracosactide (S-Cortrophin, Organon, Netherlands), 0·15 mg/m^2, was given IV for a 2-hour ACTH test (Leisti and Perheentupa, 1978a). Blood samples were taken without stasis into heparinised Pyrex tubes, which were placed immediately in an ice-water bath. Plasma was separated after the last sample. Urine was collected in glass containers, which included 5 ml HCl, 6 mol/l. Both plasma and urine samples were stored in a freezer. All samples from the same child were assayed in the same run at the end of the programme.

Submaximal bicycle ergometer tests were modified slightly from the scheme proposed by Sjöstrand (1967). The three 4-min loads were chosen individually in order to achieve the pulse rates of 80–90, 100–120, and 150–160 beats/min, respectively. In the postexercise tests the same loads were used. Then the physical working capacity for the pulse rate 180 beats/min was determined graphically. The result was expressed in watts per m^2 of surface area (1 W = 6·12 kpm/min). We prefer correction by surface area to correction by weight or by height, because, according to our calculations made on the data of Adams *et al.* (1961), the effects of age and sex are both best corrected by this method in this age group.

Peak expiratory flow rate (PEFR) (Kattan *et al.*, 1978) was determined immediately before the exercise test, and again 8–10 min after the end of the test. The highest value achieved in three attempts was used for calculation of the percentage change from the pre-exercise value. Plasma cortisol was determined with a fluorometric method (Leisti and Perheentupa, 1978a), plasma GH with a radioimmunoassay (Leisti and Perheentupa, 1978b), and urinary adrenaline with a fluorometric method (Crout, 1961). Student's 2-tailed *t* test (for differences between boys and girls), Student's paired *t* test (for differences between pre- and post-training values), and correlation coefficients were used for evaluating the results.

Results

Effect of training on working capacity. Working capacity was increased by a mean of 11% (15% in the boys, 10% in the girls; see Table). The increase was not correlated with the total number of participations in the training programme (r = −0·16), but was clearly negatively correlated with the pretraining working capacity (r = − 0·54, $P<0{\cdot}05$).

Effect of training on exercise-induced change in PEFR. A decrease of more than 15% was seen in two children during the pretraining test, and in one more child in the post-training test. Training had no clear effect on the submaximal exercise-induced change in PEFR, and the individual patterns seemed to remain consistent (Table).

Effect of training on exercise-induced hormonal response. The mean urinary adrenaline response decreased by 46% during the training period (Table). The effect was clearer in boys (55%) than in girls (29%); girls also had lower mean responses in both pre- and post-training tests. The decrease in adrenaline response correlated significantly with the increase in working capacity (Fig. 1).

Exercise induced an increase in the mean plasma cortisol level in the pretraining test, but this was no longer evident in the post-training test (Fig. 2). However, maximum cortisol levels were not significantly lower in the postexercise tests. Boys had higher maximum cortisol levels in the pretraining tests than girls, but after training there was no difference. Training had no effect on the ACTH test response (Table).

Exercise induced an increase in the mean plasma GH level in both tests (Fig. 2). Training had no effect on the GH response.

No correlations were detected between the pretraining working capacity and pretraining hormonal responses, or between the same variables measured after the training period. The plasma lactate response was not altered by the training, but boys had higher mean values in the pretraining test than girls (Table).

Discussion

Our 4-month biweekly training programme increased the physical working capacity and decreased submaximal exercise-induced responses in urinary adrenaline excretion and plasma cortisol levels in a group of asthmatic children. In contrast, GH response was not affected by the training.

As no healthy child was included, no direct comparisons can be made of the efficiency of our programme. However, the mean increase of 11% above the pretraining capacity for physical work is comparable with the increase of 15% in 6 healthy boys during a 6-month course of intensive training (Ekblom, 1969) and with the mean increase of 11% in 46 asthmatic children during a course of 5 months of swimming training (Fitch *et al.*, 1976). In most asthmatic children a 4- to 6-min period of hard exercise triggers an attack of bronchospasm (Jones *et al.*, 1962; Bierman *et al.*, 1975) with deleterious effect on the training intensity. Failure to compensate for this effect may explain the failure of some intensive training programmes (Geubelle *et al.*, 1971; Vavra *et al.*, 1971). We avoided this effect by dividing the intensive training into short bursts of activity (Strick, 1969). In accord with Fitch *et al.* (1976), training did not affect the frequency of submaximal exercise-induced bronchospasm.

Exercise-induced increases in the secretion of adrenaline (Galbo *et al.*, 1975), cortisol (Few, 1974), and GH (Sutton and Lazarus, 1976) are directly proportional to the intensity of the work. Because the loads between the two tests were unchanged in our series, our findings could be explained by assuming that the ratio of work load to physical working capacity was decreased during the training period. Unchanged plasma lactate levels indicate that the decrease in this ratio was not crucial.

In trained healthy adults, submaximal exercise (Hartley *et al.*, 1972a) or prolonged exercise before exhaustion (Hartley *et al.*, 1972b) induced a lower response in plasma adrenaline level after a 7-week period of training. However, at maximal loads or after exhaustion the responses were unchanged. Plasma cortisol and GH levels indicated no consistent changes. Basal urinary adrenaline or urinary cortisol excretion showed no changes during a period of 6 weeks' training in healthy or obese adult men (Björntorp *et al.*, 1977). In untrained asthmatic children maximum exercise induced an increase in plasma adrenaline level similar to that seen in healthy children (Chryssanthopoulos *et al.*, 1978). Our results are inferred from short submaximal exercise tests and therefore cannot be generalised. Training could induce changes in exercise responses by modifying the rate of secretion, peripheral degradation or excretion of the hormones (Few, 1974), or the rate of blood flow in the adrenal glands.

We thank the physiotherapists, Mrs Sirpa Lammi and Mrs Anne Mahlanen, for carrying out the training programme. The work was partially supported by a grant from Fisons Ltd, Finnish Division.

Dubin-Johnson syndrome with some unusual features in a Chinese family

N. S. LO, C. W. CHAN, AND J. H. HUTCHISON

University Departments of Paediatrics and Pathology, Queen Mary Hospital, Hong Kong

SUMMARY Three cases of chronic nonhaemolytic jaundice with conjugated bilirubin in the serum are described in a Chinese family. Bromsulphthalein excretion tests gave results typical of the Dubin-Johnson syndrome. Liver histology in the proband showed cytoplasmic pigment of the lipofuscin-melanin variety, and intravenous cholecystography failed to show visualisation of the gallbladder. Unusual findings included onset during the neonatal period in the proband and the presence of some iron pigment in the hepatic cells with a little canalicular cholestasis. It is suggested that the infant may have had a concomitant nonspecific hepatitis. These cases are regarded as belonging to a disease group in which the Dubin-Johnson syndrome is at one end of a spectrum. The mode of inheritance is discussed.

The hereditary defects in bilirubin metabolism are rare and incompletely understood causes of jaundice. They can be divided into two groups according to whether the raised serum bilirubin level occurs only in the unconjugated form as in Gilbert's disease (Berk *et al.*, 1970) and Crigler-Najjar disease (Crigler and Najjar, 1952), or in both the conjugated and unconjugated forms. The best known of the latter group was first described by Dubin and Johnson (1954) and independently by Sprinz and Nelson (1954). It is characterised by the accumulation of an unidentified pigment in the liver cells which is probably composed of melanin precursors which polymerise and are stored in lysosomes, although it is often called lipofuscin by pathologists (Arias, 1971). A closely similar clinical and biochemical disorder but without abnormal pigment in the liver cells was first described by Rotor *et al.*, 1948. In this paper we describe three cases of chronic nonhaemolytic jaundice with conjugated bilirubin in the serum in a Chinese family.

The proband

A Chinese male infant, the 4th child of healthy unrelated parents, was born spontaneously in the United Christian Hospital, Hong Kong on 22 March 1978. The birthweight was 3·58 kg. There was no history of maternal illness, drug ingestion, or x-irradiation. Jaundice was noted on day 2 when the total serum bilirubin (SB) level was 225·7 μmol/l (13·2 mg/100 ml). This rose to 299·3 μmol/l (17·5 mg/100 ml) on day 3 when phenobarbitone and phototherapy were started. Hb was 13 g/dl. G-6-PD deficiency was excluded. The mother's blood group was A Rh +ve, the infant's AB Rh +ve. The infant continued to feed well on a proprietary dried milk formula and on discharge from hospital on 6 April the total SB had fallen to 162·5 μmol/l (9·5 mg/100ml).

He was readmitted to the United Christian Hospital on 24 April because of persisting jaundice with a total SB of 162·5 μmol/l (9·5 mg/100 ml) of which 116·3 μmol/l (6·8 mg/100 ml) was in the conjugated form. Weight was 4·5 kg. The liver was palpable 2 cm below the right costal margin and spleen was just palpable. The urine was positive for bile intermittently but there was no excess urobilinogen on qualitative testing; there were no reducing substances. Amino-acid chromatography was normal. Hb was 10·6 g/dl; white cell count 13·0 × 10^9/l; neutrophils 15%; lymphocytes 75%; monocytes 8%; eosinophils 2%; reticulocytes 2·6%; platelets 490 × 10^9/l. Direct Coombs's test was negative. Red cell fragility normal. ESR (Westergren) 6 mm/1st hour. Blood films were negative for Hb H granules. The stools were normal in colour and consistency.

The patient was transferred to Queen Mary Hospital on 7 June. The results of serial liver function

tests between 14 June and 10 July are shown in Table 1. Other investigations included: HBsAg negative; serum α-fetoprotein not increased; α-l-antitrypsin 3·6 mmol/min per litre (normal 2·6–3·5); serum thyroxine 108 nmol/l (8·4 μg/100 ml); IgM 1·22 g/l; IgG 6·15 g/l; IgA 1·50 g/l. Prothrombin time on 14 June and 19 June 11·8 seconds (control 12·0) and 10·5 seconds (control 11·3); partial thromboplastin time 50·0 seconds (control 32·2) and 46·0 seconds (control 31·1). Antibody titres on two occasions two weeks apart showed no evidence of infection with toxoplasma, cytomegalovirus, rubella virus, or herpes simplex. The bromsulphthalein (BSP) test (5 mg/kg) showed 22·9% retention at 30 min, 19% at 60 min, and 30·9% at 120 min.

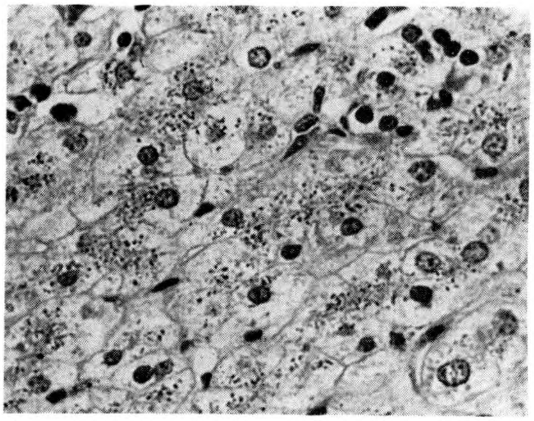

Figure *Granular pigment in liver cells. Note swollen cell just above centre of picture and 2 foci of haematopoiesis at the upper right hand corner. Binucleation and mild nuclear pleomorphism are also demonstrated. PAS after diastase with orange filter × 384.*

A Menghini needle liver biopsy on 20 June showed a specimen that was dark green in colour. Histological preparations showed that the liver had a normal lobular pattern. Most of the hepatic cells contained a brown, granular, iron-negative, non-acid fast, PAS-positive (after diastase), golden-brown fluorescent cytoplasmic pigment (Figure). Many cells also contain a little iron pigment. There are some cells with canalicular cholestasis, slight ballooning, binucleation, and variation in nuclear size. Other findings are minor and include negligible extramedullary hematopoiesis, a few mononuclear leucocytes in some portal areas, as well as iron pigment, and pigment with above-described characteristic in Kupffer cells.

Table 1 *Serial liver function tests on the proband*

	14 June	*19 June*	*27 June*	*10 July*
Total bilirubin *C – up to 26 μmol/l	119·7	121·4	80·4	58·1
Conjugated bilirubin C – up to 7 μmol/l	106	111·2	70·1	47·2
Alkaline phosphate C – 35 – 115 μmol/min per litre	1067	738	350	308
Serum AST C – 13 – 20 μmol/min per litre	94	42	56	38
Serum ALT C – 6 – 29 μmol/min per litre	37	34	61	30
Albumin C – 31 – 51 g/l	46	43	43	42
Globulin C – 23 – 40 g/l	19	20	23	23

*C—Normal values in Chinese in Queen Mary Hospital laboratory. *Conversion: SI to traditional units*—bilirubin: 1 μmol/l=0·0585 mg/100 ml.

An intravenous cholecystogram (0·6 ml Biligrafin/kg) when the total SB was 58 μmol/l (3·4 mg/100 ml) failed to show any visualisation of the gallbladder up to 4 hours.

During his stay in hospital the infant fed well and gained weight normally (6·0 kg aged 15 weeks). The icterus gradually lessened (Table 1) and the mild hepatosplenomegaly receded. The urine showed bile pigment initially but Erlich's aldehyde test repeatedly failed to show excess urobilinogen. The stools remained normal in colour and consistency throughout.

Table 2 *Liver function tests on the proband and other members of the family*

	Proband (12 weeks)	*Father (43 years)*	*Mother (33 years)*	*Sister (11 years)*	*Brother 1 (10 years)*	*Brother 2 (6 years)*

Family study

Both father (43 years) and mother (33 years) are ethnic Chinese and in good health; neither has a history of jaundice. There is no history of jaundice in the father's brother or 4 sisters, nor in the mother's 4 brothers. Their 11-year-old daughter has no history of jaundice and shows no abnormality on clinical examination. Their 10-year-old son had neonatal jaundice which persisted for longer than one month. Since then he has been subject to attacks of abdominal pain, nausea, and anorexia. Clinical examination showed a well developed boy with scleral icterus as the only abnormality. The younger 6-year-old brother had no history of jaundice but clinical examination detected undoubted scleral icterus. The results of biochemical tests on members of the family are shown in Table 2. Liver biopsy on the children was not regarded as justifiable. Unfortunately the grandparents were not available in Hong Kong.

Discussion

The presence of 'lipofuscin-melanin' pigment in the liver cells of the proband and the abnormal BSP tests in the proband and his two older brothers, who demonstrated scleral icterus, are compatible with a diagnosis of the Dubin-Johnson syndrome (DJS). Rotor's syndrome (RS) can be excluded on the liver biopsy finding of pigment deposition. There are, however, several features in the proband which are not typical of DJS. Most patients have first presented in adolescence or adult life, often with abdominal discomfort, nausea, and tiredness (Dubin, 1958; Shani *et al.*, 1970). Onset in the first 48 hours of life is exceptional, although this was the case in a Japanese neonate (Kondo *et al.*, 1975). The initial high SB levels are also atypical but they might be explained on the assumption that an early, presumably unconjugated, hyperbilirubinaemia may have been aggravated by DJS. More significant, perhaps, was the finding in the liver biopsy that while most of the cytoplasmic pigment was 'lipofuscin-melanin', some was apparently iron, whereas in typical DJS all of the pigment is 'lipofuscin-melanin'. The presence of some intrahepatic cholestasis is also not an expected finding in DJS. A possible explanation for these findings might be that this infant had a concomitant nonspecific cryptogenic nongiant cell hepatitis, particularly as there can be considerable variation in the histological appearances in neonatal hepatitis (Talbot and Mowat, 1975) and, at least in patients with α-l-antitrypsin deficiency, subclinical 'biochemical' hepatitis has been demonstrated (Sveger, 1976). The raised alkaline phosphatase and mildly raised transaminase levels could have a similar explanation although the normal ranges for these values in Chinese newborn infants are not known. On the other hand, some increase in the levels of alkaline phosphatase and transaminases have been reported in other cases of DJS (John and Knudtson, 1956; Dubin, 1958; Shani *et al.*, 1970).

None the less, the results of the BSP tests in the proband and his two male siblings are characteristic of DJS, in particular the secondary rise in BSP concentration at 120 min (Mandema *et al.*, 1960; Arias, 1961; Shani *et al.*, 1970). This pattern of BSP excretion is commonly regarded as diagnostic of the group of familial nonhaemolytic jaundice with conjugated bilirubin in the serum and it is, in fact, the only test which almost invariably gives abnormal results in these disorders (Shani *et al.*, 1970). It has been said not to be found in patients with other liver diseases (Mandema *et al.*, 1960). It would appear that while the uptake of BSP by the liver is normal in the DJS, after attaining saturation point the serum concentration falls more slowly than in normal subjects and after 30–45 minutes again increases so that the value at 120 minutes exceeds that seen at 30–45 minutes. This has been shown to be due to an impairment in the biliary excretion of conjugated BSP and related to a defect in the process by which BSP is transported from the liver cells to the bile. More detailed information can be obtained by sophisticating the BSP test to measure Tm (maximal transport rate) for BSP which is markedly reduced, whereas the relative storage capacity is normal in DJS (Wheeler *et al.*, 1960; Arias, 1961). We were unable to measure these values in the proband because of the volumes of blood which would have been required. The other characteristic but not invariable feature in DJS is absence of visualisation of the gallbladder on cholecystography (Dubin, 1958). This was the finding in the proband in our family, but its significance in the presence of a SB level of 58 μmol/l must be somewhat uncertain. Decreased levels of prothrombin and factor VII have also been reported in DJS (Seligsohn *et al.*, 1970) although in the proband in our family the prothrombin and plasma thromboplastin times were normal.

We believe that the cases in our family should be regarded as examples of DJS, and there is good evidence that the syndrome as originally described by Dubin and Johnson (1954) is but one end of a spectrum of disorders all characterised by a common functional defect in the transport of bilirubin and other substances from the liver cells to the bile. For example, Arias (1961) reported typical cases of DJS with abundant cytoplasmic pigment and of RS with complete absence of intracellular pigment in two brothers. Butt *et al.* (1966) studied 128 of 242 members of a family in which the classical findings of DJS were present. Pigmentation of hepatic cells was found in only 29 of 39 members who submitted to liver biopsy, but there was no correlation between the amounts of liver pigment and the increases in SB or BSP retention. In 8 members of two Puerto Rican families with jaundice of the DJS variety, Wolf *et al.* (1960) found a striking variation in the amount and distribution of the abnormal pigment. Furthermore, when the accumulation of pigment was slight, jaundice could still be present even without abnormal BSP retention and with normal visualisation of the gallbladder on cholecystography. While delay in the excretion of conjugated BSP with reflux of BSP in the conjugated form into the serum appears to be characteristic of DJS and is related to a defect in the canalicular membrane separating hepatocyte cytoplasm from canalicular bile (Schoenfield *et al.*, 1963), Schiff *et al.* (1959) reported a case of RS in which the BSP retained in the blood was all in the unconjugated form so that in this disorder there would appear also to be a defect in the plasma membrane separating hepatocyte cytoplasm from sinusoidal blood (Edwards, 1975).

The known coexistence of DJS and RS in one family (Arias, 1961) makes it likely that these disorders are variable manifestations of the same mutant gene, and the most generally held view has been that inheritance is in autosomal dominant fashion (Beker and Read, 1958; Mandema *et al.*, 1960; Butt *et al.*, 1966). However, while Butt *et al.* (1966) favoured autosomal dominance they also suggested that the proband in their large family and perhaps one or more of her siblings may have been homozygous for the gene whereas all the other subclinically affected persons were heterozygotes. Pereira Lima *et al.* (1966) concluded from a study of six generations of a family in which 3 members had RS, that an autosomal recessive gene was involved. On the basis of pedigree data obtained on 89 patients of 58 DJS sibships Shani *et al.* (1970) concluded that, at least in Iranian Jews, the mode of inheritance is autosomal recessive. More recently, Shani *et al.* (1973) have extended their study to 114 patients from 63 unrelated kindreds (34 Iranian) with extremely strong support for an autosomal recessive mode of inheritance, and showing a remarkably high rate of consanguinity among the parents in these kindreds. Edwards (1975) reported on the families of 44 American patients who fulfilled strict criteria for DJS. Parental consanguinity was found in at least 11 cases. He also concluded that DJS is inherited as autosomal recessive on the grounds of high frequency of consanguinity, the incidence of the syndrome among siblings of propositi, and the lack of involvement of more than one generation within each family. Edwards (1975) suggested that reports of cases inherited as autosomal dominants were probably due either to erroneous diagnoses of propositi or their relatives, or to pseudodominant inheritance of the recessive trait where an affected homozygous parent is married to an unaffected heterozygote. In our family the presence of three affected children of apparently normal parents is also compatible with an autosomal recessive inheritance. It is interesting to speculate whether the marginally raised level of conjugated bilirubin in the father's serum (8·6 μmol/l) might reflect heterozygosity for the gene.

We are grateful to Dr F. B. Johnson and Dr K. G. Ishak of the US Armed Forces Institute of Pathology for their opinions on the hepatic pathology.

Carrier detection in Duchenne muscular dystrophy

Evidence from a study of obligatory carriers and mothers of isolated cases

J. R. SIBERT, P. S. HARPER, R. J. THOMPSON, AND R. G. NEWCOMBE

Departments of Child Health, Medical Genetics, Medical Biochemistry and Medical Statistics,
Welsh National School of Medicine and University Hospital of Wales, Cardiff

SUMMARY The mean levels of serum creatinine phosphokinase (CPK) were studied in three groups of women: normal controls (57), obligate carriers for Duchenne muscular dystrophy (30), and mothers of isolated cases of this disease (35). The distribution of the levels in these groups was significantly different and was in keeping with the hypothesis that one-third of isolated cases result from new mutations. The control and carrier ranges overlapped considerably, with the level of CPK of 33% of obligate carriers coming within the 97½ centile of the normal range. Odds against an individual being a carrier were derived for specific mean values of CPK. They should be considered with genetic information using Bayes's theorem. The mean CPK levels in obligate carriers showed significant familial clustering. This may have implications in carrier detection.

The primary metabolic defect in Duchenne muscular dystrophy remains unknown, but a raised level of serum creatinine phosphokinase (CPK) has until now been the best available method for detecting the female carrier in this disease (Schapira *et al.*, 1960). The fact that carrier and normal ranges overlap makes the interpretation of values within the normal range difficult, even when biochemical and genetic information is integrated. The mothers of isolated cases are a particular problem, and it has been suggested (Roses *et al.*, 1976) that almost all such women are carriers, although genetic theory and the results of CPK studies do not confirm this.

The present work, based on a population study of Duchenne muscular dystrophy in Wales, assesses the efficacy of the serum CPK in carrier detection, and re-examines the problem of the proportion of isolated cases which represent new mutations. The evidence for familial correlation of CPK levels in carrier women, which is of considerable practical consequence in genetic counselling, is also investigated.

Methods

All families in Wales known to contain at least one member with Duchenne muscular dystrophy were investigated as part of a more general genetic study of the disorder in Wales in which complete ascertainment was attempted. 75 such families have so far been studied. Patients were diagnosed as having Duchenne muscular dystrophy if they had had a severe disability before age 12 years and had greatly increased serum CPK, in addition to the recognised clinical features of the disease. Great care was taken to differentiate families with the Becker form of X-linked dystrophy.

Three groups of women were studied: (1) obligate carriers, a woman with at least one son and one other male relative affected or with two or more affected sons; (2) mothers of isolated cases; (3) healthy nonpregnant female volunteers of comparable age range.

Three separate blood samples were taken from these women with at least 3 days' interval between each venepuncture. Only one sample could be taken from 3 elderly obligate carriers. We did not investigate girls under 15 years. All blood samples were taken under conditions of normal activity, and heavy exercise during the preceding 24 hours was avoided. All CPK levels were determined on an Unicam SP 1800 recording spectrophotometer by the Boehringer (Mannheim) UV-System 10 assay

method by one of us (R.J.T.). Blood samples were either separated within 2 hours and assayed directly or were stored at 4°C overnight. This made no significant difference to the recorded activity. Care was taken to protect sera from light.

Results

We studied the mean of the 3 serum CPK values for each woman. The distribution of CPK levels in normal controls (57), obligate carriers (30), and mothers of isolated cases (35) is shown in the Figure. From these distributions it can be seen that the normal range and the range for obligate carriers overlapped to a great extent. Approximately 33% of obligate carriers came within the 97½ centile for normal range. Three of our control women had mean CPK values of at least 100 mU/ml. The distributions are not gaussian but if logarithmic CPK values are used they approximate to a distribution of this form, with the means and SDs as shown in Table 1.

The odds against an individual being a carrier can be derived for specific values of serum CPK, and are shown in Table 2. They can be combined with the genetic odds and other information using Bayes's theorem, enabling precise odds to be given for values of CPK within the normal range. Details of the working of these calculations can be found in textbooks of medical genetics, such as Emery (1976).

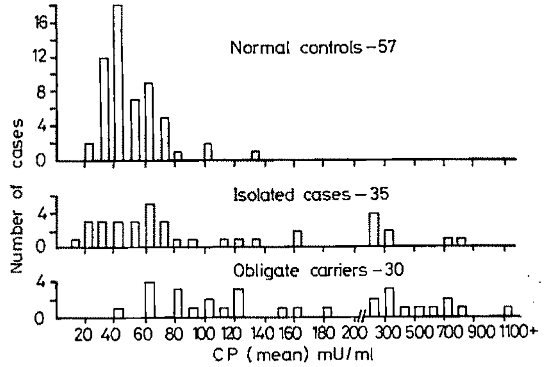

Figure *Distribution of serum CPK levels in normal controls, isolated cases, and obligated carriers.*

Table 1 *Means and standard deviations of cases*

	No. of cases	*Geometric mean*	*Mean log CPK*	*SD log CPK*
Normal controls	57	49·8	1·698	0·147
Obligate carriers	30	188·1	2·274	0·426
Mothers of isolated cases	35	83·9	1·924	0·417

Table 2 *CPK (mean of observed values) and likelihood ratio for carrier status*

Range of CPK	*LR*	*Range of CPK*	*LR*
<40	8·221	120–	0·0782
40–	8·033	130–	0·0398
50–	6·103	140–	0·0204
60–	3·831	150–	0·0106
70–	2·167	160–	0·00553
80–	1·157	170–	0·00292
90–	0·598	180–	0·00156
100–	0·305	190+	<0·001
110–	0·154		

LR = likelihood ratio.

Take for instance the case of a daughter of a known carrier. She has a prior probability of being a carrier herself of one in 2. However, information from CPK values, and any normal sons she has must also be considered. If she for instance had a mean CPK of 45 mU/ml, and a normal son, odds of approximately one in 8 for CPK value, and one in 2 for the normal son must be combined with the prior probability. Using Bayer's theorem this gives a final probability for this woman being a carrier of one in 17, significantly from the one in 2 original figure.

The CPK values for the three groups of women we studied differ significantly. Comparing normal controls with obligate carriers $t = 7{\cdot}20$ $P<0{\cdot}001$, and normal controls with mothers of isolated cases $t = 9{\cdot}09$ $P<0{\cdot}004$. If obligate carriers are compared with mothers of isolated cases $t = 3{\cdot}34$ $P<0{\cdot}002$.

The mean serum CPK values of the 30 obligate carriers is shown in Table 3 arranged within families. The ratio F of between family variance to within family variance based on logs of means of replicates is 3·96 $P<0{\cdot}05$. There is thus a significant familial clustering of CPK values.

Discussion

Several methods have been suggested for detecting carriers of Duchenne muscular dystrophy. Changes in muscle histology and histochemistry have been noted in some carriers, but many have given normal results. There is less discrimination between normal subjects and carriers than with serum CPK estimations. Qualitative electromyography is not of value in carrier detection; however quantitative work does show some discrimination but this method does not appear to improve the accuracy of detection based on serum CPK estimations. There is no suitable marker gene close enough to the Duchenne locus on the X chromosome to be of value in linkage work, and there is a greater overlap in other serum enzyme levels between normal subjects and carriers than with serum CPK estimations. Thus although this CPK method is far from ideal no better alternative is available. The subject has been reviewed by Emery (1969) and Gardner-Medwin *et al.* (1971).

Other workers as well as ourselves have found that control and carrier ranges of CPK values overlap greatly (Table 4). This overlap may represent variable X chromosome inactivation in the heterozygous females, as well as lack of relationship of the test to the primary biochemical defect of the disease.

We found the calculation of the odds of a woman being a carrier of Duchenne dystrophy at a certain CPK value within the normal range adds considerably to the precision of genetic counselling, as have the studies of Emery (1969) and Dennis *et al.* (1976). These odds must be combined with gentic information by the use of Bayes's theorem.

Roses *et al.* (1976) suggested, based on the study of phosphorylation of red-cell membrane proteins, that the mothers of almost all isolated cases are carriers, possibly as a consequence of unequal mutation rate between the sexes. The distribution of CPK values of the three groups of women we studied (obligate carriers, mothers of isolated cases, and normal controls) differs significantly, which argues strongly against this hypothesis. Our results are compatible with the classical genetic hypothesis of Haldane (1935) that one-third of isolated cases in a lethal X-linked recessive disorder are the results of new mutations. If this hypothesis is correct, mothers of isolated cases in our series should have a mean log CPK of 2·082 with a SD of 0·445. The values of CPK in these women are compatible with this, and give no grounds for rejecting the classical hypothesis. The implications for genetic counselling for families of isolated cases are considerable. Pickard and his colleagues (1978) recently presented data on lymphocyte capping on a variety of neuromuscular conditions, including mothers of boys with Duchenne dystrophy. They suggested that new mutations may be more common than Haldane thought. However they have not clearly differentiated obligate carriers on family history from mothers of isolated cases, nor have they analysed statistically the differences between these two groups of women and normal controls. Furthermore they did not state whether their normal controls are women of child-bearing age or not.

Our results show that correlation within families may exist for levels of CPK in carriers; this has important implications in carrier detection. Thus a relatively low CPK level in a potential carrier where obligate carriers in the family are also known to have a low CPK level may need to be interpreted with caution. More extensive data on families with multiple obligate carriers will be required to assess accurately the degree of such correlation and to allow it to be used with other information.

We thank the paediatricians, neurologists, and other clinicians in Wales who have allowed us to study their patients, and the families themselves for their cooperation. We acknowledge gratefully support given to one of us (P.S.H.) by the Muscular Dystrophy Group of Great Britain. We thank members of the Llandough Ladies' Circle, and members of the staff at the University Hospital of Wales for being controls.

Cytomegalovirus and blood transfusion in neonates

J. W. T. BENSON, S. J. BODDEN, AND J. O'H. TOBIN

Department of Paediatrics, John Radcliffe Hospital, and Virus Laboratory, Churchill Hospital, Oxford

SUMMARY A fatal case of neonatal cytomegalovirus (CMV) infection attributed to exchange transfusion is described. The incidence of CMV transmission by exchange and other neonatal transfusion was studied, and the use of CMV antibody-free blood for these procedures was shown to be effective in preventing CMV infection in neonates.

Cytomegalovirus infection is a well recognised complication of blood transfusion, leading in some cases to the post-transfusion syndrome. Recent studies have shown that about 25% of exchange transfused neonates become infected with cytomegalovirus (CMV), and although transfusion-acquired CMV infection in infants seldom causes obvious illness, it may do (Yeager, 1974; Tobin *et al.*, 1975; Pass *et al.*, 1976).

An infant born in Oxford apparently died from CMV infection after transfusion. We describe this fatal case and report the results of our studies into the effectiveness of CMV antibody-free blood in avoiding transfusion-acquired infection.

Patients and methods

Between April 1975 and October 1976, 80 surviving babies were transfused in the special care unit at the John Radcliffe Hospital; 64 of them were followed up. 18 received exchange transfusions of between 200 and 1500 ml blood (mean 550 ml). The blood used was less than 4 days old and preserved in acid-citrate-dextrose. 46 received simple transfusions of between 5 and 150 ml (mean 30 ml). Initially blood for simple transfusions was obtained from 'walking donors' who were staff members of the special care or maternity units. The blood was taken into a sterile heparinised syringe and given straight to the baby. During the last 6 months of the study most simple transfusions were of CMV antibody-free blood from the Oxford Regional Transfusion Service supplied in 50 ml minipacks (Gunson *et al.*, in preparation), between one and 7 days old.

42 babies were studied retrospectively and 22 prospectively. The retrospective group were seen at least once between ages 10 weeks and 14 months, at which time the babies were physically examined and their development, head circumferences, and hearing were assessed. Blood for CMV complement-fixation tests and immunofluorescent antibody (de Silva *et al.*, 1977) was taken from both mother and baby, and a throat swab and urine were taken from the baby for virus isolation on human embryo fibroblast cultures. In the prospective group blood was taken from the mother within 2 weeks after transfusion of the baby, and a throat swab and urine were collected from the baby for virus culture within 3 days of transfusion. The mothers and babies in this group were seen again between 3 and 6 months after transfusion, and 8 of them were seen a second time at between 6 and 9 months; at these times the baby was clinically assessed and a throat swab, urine, and blood were taken for virus investigation as in the retrospective group.

All the 42 babies studied retrospectively received blood from donors who had not been screened for CMV antibody, although subsequently the CMV antibody titres of all blood donors were determined for 33 of the babies. For the remaining 9 babies the CMV titre of at least one donor could not be ascertained. In the prospective group of 22 babies one or more donors for 3 babies were not available for CMV serological tests. 16 babies were given CMV antibody-free blood deliberately.

97 infants aged between 5 and 18 months, who had not been transfused and who were attending an infant welfare clinic, or were in hospital, served as controls; they were tested for CMV infection either by virus isolation or serology.

Results

In the first 13 months of the study, before a policy of selection of CMV-negative donors was introduced,

CMV-free blood	'Top up'	14	0	0	0	0
Controls, not transfused	Infants (5–12 months)	42	2	2	NT	4·8
	Infants (5–18 months)	55	2	NT	2	3·6

NT = not tested.

4 (25%) of 16 exchange transfused babies and 4 (12·5%) of 32 receiving simple transfusions became infected with CMV. During the last 5 months of the study, the 2 babies exchange transfused and all 14 receiving simple transfusions of CMV antibody-free blood remained uninfected (Table 1).

The blood donor CMV status was determined by immunofluorescence (IF) (de Silva *et al.*, 1977) for 52 of the 64 babies. 21 babies received blood from at least one CMV antibody-positive donor and 8 (38%) became infected, while the 31 babies who received only CMV antibody-free blood remained uninfected. Comparing these two groups by the χ^2 test the result was significant ($\chi^2 = 11·54$, $P<0·001$). None of the 12 remaining babies who received blood from a donor of unknown CMV status became infected. The CMV infection rate by donor antibody status in those exchange transfused is given in Table 2.

Exchange transfusions. The 4 babies who became infected after exchange transfusions received on average 864 ml blood from 4 donors for each baby, compared with an average of 480 ml from 2 donors for those 14 uninfected. Three of the 4 babies infected after exchange transfusion showed no clinical signs attributable to CMV during the period of observation. The 4th, who subsequently died, is described below.

Case report

A 33-year-old group O Rhesus-negative mother who had previously had 3 liveborn babies and one stillborn baby affected by rhesus iso-immunisation, became pregnant again with a rising Rh antibody titre during the 2nd trimester. She refused intrauterine transfusion and underwent plasmapheresis, a total of 50 units of plasma being exchanged over 10 weeks. The Rh antibody level remained fairly steady and she was delivered by caesarean section at 30 weeks' gestation. She had received a 40-hour course of betamethasone since an amniocentesis 3 days before delivery had shown the amniotic fluid palmitate to be 19 mmol/l. Her baby daughter weighed 1300 g at birth and had an enlarged liver and spleen, but was not hydropic. The baby's blood group was O Rh positive, her cord plasma bilirubin was 100 µmol/l (6 mg/100 ml), haemoglobin 7·3 g/dl, reticulocytes 30%, and the direct Coombs's test strongly positive. She was given 4 exchange transfusions during the next 2 days through an umbilical venous catheter with 0–2-day old, partially packed ACD blood. Phototherapy was given for the first 3 days of life and the bilirubin level had fallen to 70 µmol/l (4 mg/100 ml) by day 6. Twelve hours after the last exchange transfusion she was given 5 ml platelet concentrate and 30 ml fresh heparinised blood as she had rectal bleeding and a platelet count of 39×10^9/l. Feeds of expressed breast milk were gradually introduced 5 days after the onset of the rectal bleeding, and although she required IV alimentation for 9 days, she apparently made a complete recovery from her haemolytic disease by the 12th day of life.

Table 2 *CMV infection in exchange transfusions according to donor antibody status*

CMV antibody status of donors	*No. of babies tested*	*Infected babies*	
		No.	*%*
+	7	3	36
UK*	4	1	
−	7	0	0

*Unknown.

Six days later she became mottled and less active and her temperature became unstable. She was treated with gentamicin, cloxacillin, and carbenicillin, although bacteriological reports subsequently showed no pathogens. The antibiotics were changed to chloramphenicol and penicillin when her condition did not improve. Her white blood count rose to $45·3 \times 10^9$/l on the 24th day of life, with $15·4 \times 10^9$/l neutrophils, $18·1 \times 10^9$/l lymphocytes, and $10·8 \times 10^9$/l eosinophils.

On the 27th day she was noted to be jaundiced and her liver and spleen again became enlarged. Her total bilirubin rose to 425 µmol/l (25 mg/100 ml) with 200 µmol/l (11·5 mg/100 ml) conjugated. Her aspartate transaminase was 970 IU/l, lactate dehydrogenase 3900 IU/l, and alkaline phosphatase 165 IU/l. Hepatitis B antigen was not detected, but CMV was isolated from urine and a throat swab taken at 23 days of age, and from CSF taken 8 days later. Her condition steadily deteriorated. She developed gross ascites and anaemia, her plasma sodium level fell, and she became hypoalbuminaemic. Her platelet count fell and she developed haematuria and a petechial rash. She became oliguric and despite treatment with albumin, blood transfusions, frusemide, and physiological doses of hydrocortisone, she died at age 28 days. Permission for necropsy was not obtained.

The mother's blood taken at 20 weeks' gestation and at delivery contained CMV IgG antibodies at a titre of 1:64 but no specific CMV IgM or IgA was detected in either specimen. The baby's cord blood total IgM was <25mg/100 ml (<30 IU/ml) but none was available for testing for specific CMV antibodies. Three of the 4 blood donors for the exchange transfusions were found retrospectively to be CMV antibody positive. The donor of a small blood transfusion given on day 5 was also CMV positive. The CMV antibody status of the platelet donation was not determined.

Simple transfusions. The 4 babies who became infected after simple transfusions showed no clinical signs of infection. At follow-up between 5 and 13 months of age, 3 were still excreting virus and all had antibody to CMV. Three were normal on examination. The 4th was mildly retarded, probably as a result of repeated severe apnoeic attacks after delivery at 28 weeks' gestation.

Maternal CMV infection. Sera from 6 of the 8 mothers of infected babies were available for testing from late pregnancy and again when the babies were seen for follow-up. Five of these mothers had antibody to CMV before delivery, 4 of whom showed no change in titre. One showed a 16-fold rise in complement-fixation titre from 1:8 to 1:96 at 8 months after delivery, indicating reinfection or reactivation of her previous CMV infection. The 6th mother who had no CMV antibody before delivery showed a raised titre (1:32) when tested 5 months postpartum.

Discussion

Although cytomegalovirus infection after blood transfusions usually produces no clinical disease, in a few patients it can produce post-transfusion mononucleosis (Foster and Jack, 1969), and this syndrome can occur at any age including the first few weeks of life (Tobin *et al.*, 1975). Cytomegalovirus infection can however be accentuated by immunosuppression, especially in patients undergoing renal and other transplants in whom primary infections can cause worrying symptoms and may occasionally lead to a fatal outcome. It is also an occasional complication in leukaemic and lupus patients and in others on immunosuppressive treatment.

It cannot be absolutely certain that the fatal case reported here acquired CMV infection from blood transfusion. However, there was no serological or other laboratory or clinical evidence that this was a congenital infection; the mother had neither IgA nor IgM CMV antibodies at any time during pregnancy and the isolation of virus from urine, throat swabs, and CSF during the illness would indicate a generalised viraemia in the baby.

Although the neonate usually does not seem to be any more likely to produce overt symptoms after CMV infection from transfusion than older people, such babies may be a danger to their mothers who usually are infected by them during the ensuing months. If these mothers happen to be pregnant and nonimmune, it is possible that the fetus could be affected by cytomegalic inclusion disease. As the usefulness of transfusion with CMV-free blood is still open to discussion, evidence on the effectiveness of screening blood for CMV antibody, and the demonstration that infection can be so prevented by its use are worth while.

For CMV antibody determination we used the IF antibody test (de Silva *et al.*, 1977) as it is more sensitive than the complement-fixation (CF) test and quicker to perform, a result being obtained in 2 hours as opposed to the overnight incubation required for the CF test. Our results using this IF test in exchange transfused babies indicates that it is satisfactory for blood screening. Although the numbers are not great, the difference between those infected after receiving CMV-positive blood and those not infected after negative blood was significant.

It is obvious that all blood cannot be screened for CMV antibodies by all blood transfusion centres, but we feel that there should be more studies to see if the use of CMV-negative blood in exchange transfusions of babies is worth while. These should be parallel to studies in patients undergoing transplants and heart operations where CMV infection in the nonimmune can be prevented by screening blood and kidney donors and using material only from those without CMV antibody.

We thank Miss Eileen Hopkins and her staff at the East Oxford Health Centre for specimens from infants; Dr G. R. H. Gunson, Oxford Regional

Blood Transfusion Service, for samples from blood donors; Dr D. Knight for help with the case history; and Professor J. P. M. Tizard and Dr J. D. Baum for encouragement and advice.

Comparative trial of manual and mechanical percussion technique with gravity-assisted bronchial drainage in patients with cystic fibrosis

MAUREEN MAXWELL AND AILEEN REDMOND

Royal Belfast Hospital for Sick Children

SUMMARY Chest physiotherapy still remains one of the most important aspects in the treatment of chest complications of cystic fibrosis. A mechanical device that allows the patient with cystic fibrosis to do his own chest physiotherapy will be of great benefit if it is as effective as manual percussion. 14 patients with cystic fibrosis using mechanical and manual percussion physiotherapy were studied by measuring sputum volumes, and FEV and FVC. Results with the mechanical percussor were as good as with the manual percussor and, therefore, it would be reasonable for the older patient to use the former on his own.

The life expectancy of patients with cystic fibrosis (CF) has greatly improved in recent years (Anderson and Goodchild, 1976), and most CF clinics are now having to extend their care to the adolescent and young adult. Any patient, as he grows older, resents having to depend on another adult for chest physiotherapy. We have, therefore, compared the use of manual with mechanical percussion as the latter would enable the patient to do his own treatment and thus gain independence (Denton, 1962).

Patients and method

14 patients with CF between ages 7 and 21 years who could co-operate with the use of the Vitalograph spirometer were chosen. At the time of testing the patients were in clinical remission. 11 were normally sputum producers and 3 produced sputum only when they had exacerbations of chest infection.

Apparatus. The mechanical percussion unit, Equi-Med percussor* (Fig. 1) operates on 230 volts at 200–3200 strokes/min using a 10-speed selector switch. All the children were tested using 230 strokes/min. The percussor weighs 1·588 kg. The unit is applied to the chest wall, the percussor head being directly in contact with the rib cage (Fig. 2) over the selected segment of the lung to be drained.

MAUREEN MAXWELL, lecturer in physiotherapy

The percussion was interrupted only for expectoration and change of position.

Experimental conditions. Patients were treated on one day with manual and the next with mechanical percussion, random sampling tables being used to determine the initial method. Each patient was treated at the same time each day. The Vitalograph readings were FEV_1, FVC, FER, the readings being taken at 10-min intervals for one hour after treatment. Amounts of sputum were measured by weight.

The postural drainage positions were those described by Kendig and Chernick (1977).

Lower lobes
Four segments, right and left, anterior, posterior, lateral, superior.

Middle and lingular lobes
Upper lobes
Two segments, right and left, anterior, apical, using a treatment time of 32 minutes for each period. The various lobes were treated in the same order in each patient and all segments were treated for a period of 2 minutes.

Results

The FEV (Table 1) and FVC data (Table 2) show there was no obvious difference between mechanical and manual treatment, and this was confirmed by statistical analysis. Amounts of sputum are shown in Table 3. It was suggested by the parents that the children coughed up more sputum when using the mechanical percussor at home but, when the actual amounts were measured, there was no overall difference.

Discussion

All patients and all parents (with the exception of one) preferred mechanical percussion. Patients found it was less tiring and that it gave them a sense of support. Most parents admitted that they felt that they could not do the manual technique as well as the trained physiotherapist and felt the children were not gaining maximum benefit. However, they thought the children received maximum benefit with the mechanical percussor. All patients could treat some segments themselves, particularly the upper lobes. The main disadvantage for the patient was the noise of the percussor. We find that small babies adjust to the mechanical percussor and often fall asleep during treatment. The youngest child who could use the percussor independently was 13 years. Small children could not reach the basal segments of the lower lobes and found the middle lobe difficult, although they could treat the upper ones.

It would appear that mechanical is as effective as manual percussion. The percussor costs about £85 (plus VAT). This is a large sum to spend, particularly as manual percussion can be just as effective. The main advantage of a mechanical percussion unit is that a teenage or adult CF patient can use it entirely on his or her own and thus be independent.

We thank Dr Tom Hassard, Department of Medical Statistics, Queen's University, Belfast, and Dr F. Stanford, Consultant Chest Physician, Belfast City Hospital.

Serum C-reactive protein test in diagnosis of septic complications of cerebrospinal fluid shunts for hydrocephalus

R. BAYSTON

Children's Hospital, Sheffield

SUMMARY Serial tests for serum C-reactive protein (CRP) were carried out on 40 children undergoing cerebrospinal fluid shunt surgery, to determine the pattern of appearance and disappearance of CRP in relation to this type of operation, in the absence of postoperative complications. Samples of sera from a further 268 children, 79 of whom presented after shunt surgery with symptoms suggesting infective complications related to the shunt, were examined for CRP. The results showed that, while the test is negative in uncomplicated colonisation of ventriculo-atrial shunts, it is reliably positive in patients with colonised ventriculo-peritoneal shunts, ventriculitis, or shunt nephritis.

Tillet and Francis (1930) described a substance which was present in the sera of patients in the acute stage of pneumonia. Anderson and McCarty (1950) described the use of a capillary test for this C-substance (now called C-reactive protein, CRP) in the serum to monitor the severity of the disease in rheumatic fever, and other workers used it to assess the presence and severity of other inflammatory conditions (Bunim *et al.*, 1952). The exact nature and origin of CRP is still unclear. Immunological studies show that it is a globulin (Wood *et al.*, 1954) but little is known about its site of origin, fate, or function (Wood, 1953; Kushner and Kaplan, 1961). CRP is an abnormal protein as it is not found in the serum of a healthy person, but appears in a matter of hours after onset of tissue damage or destruction, regardless of the cause, and disappears equally rapidly after the destructive process has ceased. CRP is not subject to normal variation, as is the erythrocyte sedimentation rate (ESR), and is independent of the haematocrit. In these respects it is generally found to be more useful and sensitive than the ESR as a reflection of acute inflammatory disease.

Sera from patients with cerebrospinal fluid (CSF) shunts were tested for presence of CRP to assess its usefulness as an adjunct to other diagnostic tests for septic complications associated with the use of these devices.

Children's Hospital, Sheffield
R. BAYSTON, research fellow

Patients and methods

308 children admitted for insertion of a first shunt, revision of an existing one, or for investigation of possible shunt complications, were studied. Their ages ranged from 2 weeks to 15 years. All had hydrocephalus and, in many, this was associated with spina bifida. In others it was posthaemorrhagic, postmeningitic, or 'congenital'.

Blood was taken from each child preoperatively and then on days 5 and 10 postoperatively. A group of 40 of these children also had blood taken on the first day after operation. Samples were routinely taken from children at these times as a means of detecting shunt colonisation by the *Staphylococcus albus* antibody test (Bayston, 1972, 1975). Many were followed up as outpatients and further blood samples taken. In this hospital the Holter valve is used exclusively and both ventriculo-atrial and ventriculo-peritoneal routes are used.

Serum CRP was measured by the capillary method (Anderson and McCarty, 1950) using commercially prepared antiserum (Difco Laboratories Ltd). To perform the test, 25 μl of patient's serum are run into a capillary tube, followed by an equal volume of antiserum. The tube is rocked to and fro to mix, and one end is plunged into a block of modelling clay. The tube is kept upright in this manner at room temperature for 8 hours or overnight. If CRP is present a complex is formed which falls to the bottom of the column of fluid in the tube. The height of the column of precipitate is measured in millimetres to give a semi-quantitative result.

Results

Of the 308 children studied, 229 did not develop any clinical abnormality or sign of shunt complications. 40 of these children had had CRP estimations carried out on samples taken on the day after operation, as well as preoperatively, and on the 5th and 10th postoperative days. 21 of these had insertion or revision of an atrial shunt, 17 had insertion or revision of a peritoneal shunt, and a further 2 had exploration of a peritoneal shunt limited to the distal end. The CRP results in these 40 children are shown in Table 1. All gave a positive test after the operation on day 1, but by day 5 the test was negative except in the 17 children in whom insertion or full revision of a peritoneal shunt had been performed. All had become negative by day 10. In the remaining group of 189 patients who did not have CRP estimations carried out on the day after operation but in whom there were no complications, all had negative CRP tests preoperatively and on the 10th day postoperatively. Of the 87 patients in this group who had full revisions of peritoneal shunts, 79 had positive CRP tests on the 5th postoperative day.

The remaining 79 children subsequently presented, either at outpatient visit or on direct hospital admission, with one or more of the signs and symptoms of shunt colonisation. The results in these children, and their final diagnoses, are shown in Table 2. Shunt colonisation caused by *Staphylococcus pyogenes* gave rise to a positive test in all 7 patients. In 8 cases of ventriculitis and 8 of shunt nephritis the CRP test was uniformly positive. 11 cases of peritoneal shunt surgery showed a different pattern of results from those shown in Table 1, in that the CRP test did not become negative by day 10 postoperatively, and was persistently positive when checked thereafter.

All 16 cases of uncomplicated atrial shunt colonisation due to *S. albus*, where there was no evidence of shunt nephritis or ventriculitis, gave negative CRP tests.

Table 1 *Serum CRP results associated with shunt surgery in the absence of complications*

	Positive CRP			
	Before operation	*After operation (days)*		
		1	*5*	*10*
Insertion or revision of atrial shunt (n = 21)	0	21	0	0
Insertion or revision of peritoneal shunt (n = 17)	0	17	17	0
Limited exploration of peritoneal shunt (n = 2)	0	2	0	0

Table 2 *Serum CRP results and final diagnoses in 79 children with suspected shunt sepsis*

Diagnostic group	*Positive* (*n*=*56*)	*Negative* (*n*=*23*)	*Subtotal* (*n*=*79*)
Uncomplicated atrial shunt colonisation (*S. albus*)	0	16	16
S. pyogenes shunt colonisation	7	0	7
Ventriculitis	8	0	8
Shunt nephritis	8	0	8
Colonised peritoneal shunt (*S. albus*)	11	0	11
Intraventricular haemorrhage	2	0	2
Urinary tract infection	6	4	10
Respiratory tract infection	9	3	12
Otitis media	5	0	5

The remaining 29 children in whom there was no evidence of sepsis of the shunt or central nervous system gave variable results.

Discussion

The CRP test has been used to monitor postoperative progress in general surgery (Fischer *et al.*, 1976), and it has other applications, but its use in shunt surgery and its subsequent follow-up has not been described. The results of the test after shunt surgery in the absence of postoperative complications are shown in Table 1, and show that CRP is also present in the serum on day 1 postoperatively. If such operations are classified into three groups, the test will give negative results by day 5 in operations on atrial shunts; it was negative in the 2 patients in whom only limited exploration of the intraperitoneal portion of the shunt was carried out. However, in the 17 patients in whom a more extensive procedure was carried out (revision or insertion of a peritoneal shunt) the test was still positive on day 5. The presence of CRP in the serum after shunt operation is presumably due to tissue damage incurred as a result of incision and dissection. To insert a catheter from the neck to the peritoneal cavity a tunnel has to be created over the rib cage with the use of much blunt dissection. This would explain the prolonged disappearance time for CRP in these cases.

In those 11 cases where the CRP test was persistently positive after operation, a diagnosis was made of colonisation of the shunt involving only the lower catheter. The children presented with signs suggesting blockage rather than colonisation (Bayston and Spitz, 1977) and the peritoneal reaction resulting from the flow of bacteria-laden CSF was found at operation to be causing partial obstruction of drainage. The reactive changes in the peritoneal cavity would explain the persistently positive CRP test.

The 7 cases of colonisation by *S. pyogenes* were all associated with postoperative infection of the scalp and/or neck wounds. Such colonisation is usually confined to the outer surface of the shunt, but because of the histolytic properties of the organism the infection rapidly tracks down the outside of the catheter and organisms enter the blood stream. There is considerable inflammatory response and it is therefore not surprising that the CRP test is positive in such cases.

However, in cases of colonisation of atrial shunts with *S. albus*, where the organisms are confined to the lumen of the shunt (Bayston and Penny, 1972) and enter the blood stream directly from the end of the distal catheter, there is no inflammatory response unless there is also involvement of the cerebral ventricles. In those uncomplicated cases without ventricular involvement, CRP is absent from the serum and diagnosis is confirmed by the finding of a positive *S. albus* antibody test.

Where the preoperative investigation of a patient includes a contrast or air ventriculogram, the finding of CRP in the serum the next day strongly suggests infective ventriculitis, and insertion of a shunt should be delayed until such infection has been ruled out, if possible by examining the ventricular fluid.

In a case of long-standing colonisation of atrial shunts, a positive CRP test often indicates the onset of shunt nephritis, even before haematuria is seen. At this stage the finding of high antibody levels to *S. albus* together with low serum complement levels confirms immune complex nephropathy.

The CRP test is nonspecific and positive results may be due to inflammation or tissue necrosis from any cause. Of 12 children whose symptoms were found to be due to a respiratory infection, 9 gave a positive CRP test. By subjective assessment, the illness in these patients was more severe than in the remaining 3. The 9 patients with positive CRP tests who had respiratory infections also had bacterial infections, whereas the remaining 3 were thought to have viral infections. Similarly the 5 cases of acute otitis media which showed a positive CRP test were found to be bacterial.

The test was also positive in 10 patients with urinary tract infection who presented with fever among their symptoms. Although precise details are not known, it is possible that those children with infection and ureteric reflux probably had renal involvement, and would be more likely to give a positive CRP test than those with cystitis alone.

As the purpose of this paper is to investigate the place of the CRP test in diagnosing septic complications of CSF shunts, the 22 children in whom CRP was found in the sera but in whom there was no involvement of the shunt may be thought of as false positives. However, if the test is found to be positive such possible causes as otitis media and infection of the respiratory and urinary tracts can be excluded easily and rapidly.

Conclusions

The results of the study suggest that the unexpected finding of CRP in the serum in a patient with a CSF shunt should always be vigorously investigated. The test is useful for detecting preoperative ventriculitis after ventriculography, and colonisation of ventriculo-peritoneal shunts. It is often the first indication of the onset of early shunt nephritis in those patients with long-standing colonised atrial shunts.

I thank the staff of the Paediatric Surgical Unit of the Children's Hospital, Sheffield, for their cooperation. The patients were under the care of Professor R. B. Zachary, Mr L. Spitz, and Dr J. Lorber. The work was supported by the Association for Spina Bifida and Hydrocephalus and the RICHARD Fund, Sheffield.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onward all manuscripts submitted should accord with the new style.

Short reports

Two cases of perinatal listeriosis

M. H. ROBERTSON, N. G. MUSSALLI, T. A. AIZAD, J. M. OKARO, AND
G. S. BANWELL

Departments of Bacteriology, Obstetrics and Paediatrics, Princess Alexandra Hospital, Harlow, Essex

SUMMARY Two cases of neonatal listeriosis are described. The incidence in the UK is given and the treatment of the pregnant woman is briefly discussed.

Perinatal listeriosis is believed to be rare in Britain but it may be under-reported. It carries a high mortality for the child but the mother suffers only a mild illness. Two cases are described in which the infants survived. One of these is thought to be the first description of a case treated during pregnancy in this country.

Case reports

Case 1. A 35-year-old Englishwoman, married to a Greek and living in Germany attended our antenatal clinic at approximately the 35th week of her 2nd pregnancy. A previous pregnancy 6 years previously had been normal.

Admitted in early labour 8 days later her temperature was 36°C and the pulse rate 84/min. She had a spontaneous delivery of a baby girl who had difficulty in breathing. The placenta was retained and removed manually, and a postpartum haemorrhage required blood transfusion during which her temperature rose to 38°C.

Although a transfusion reaction could not be excluded clinically a course of gentamicin 80 mg intramuscularly 8-hourly was begun lest infection were present. A transfusion reaction was subsequently excluded. Unfortunately a blood culture was not taken until the next day; it showed no growth. A high vaginal swab and urine sample, also taken next day, yielded no significant organisms. Her pyrexia persisted throughout the day rising to 38·1°C with rigors. Urinary output was satisfactory and her general condition good. At this stage the patient's history was re-examined and it was found that on the day before admission she had had a temperature of 38°C with cold sweats and rigors, and she had had several 'flu-like episodes' during her pregnancy in Germany before arrival here. Her illness had been vague and there had been no diagnosis; she had been given several drugs which we could not identify. Pyrexia lasted until 2 days after delivery reaching a maximum of 39°C and then settled. There was no evidence to suggest genital tract infection and her subsequent progress was uneventful.

The baby weighed 2980 g and was assessed as 36 weeks' mature. She had Apgar scores of 1, 5, and 8 at one, five, and ten minutes respectively and had to be intubated. Her respiratory difficulties continued and blood–gas and bicarbonate studies suggested a perfusion-diffusion defect. After 16 hours she became jaundiced. As the father was Greek glucose-6-phosphate dehydrogenase deficiency was looked for and excluded. At 36 hours she developed a purpuric rash. A full infection screen was carried out including antibody screen for rubella, cytomegalovirus, measles, herpes simplex, and toxoplasma. None of these was positive and the platelet count was normal. Two separate blood cultures and swabs from the eyes, nose, throat, skin, and umbilicus all grew *Listeria monocytogenes* type 4. The CSF was sterile but contained $0 \cdot 014 \times 10^9$/l white cells, 75% polymorphs. The urine was sterile.

Once the diagnosis had been made in the baby the mother's blood was again cultured, but still with negative results. Urethral, cervical, and vaginal swabs were again negative. Serological tests carried out on the day of delivery and 15 days later each gave an agglutination titre of 2048 against *Listeria*. The placenta was not available for examination but it looked healthy and complete and weighed 700 g.

A course of flucloxacillin and ampicillin equally (Magnapen) 125 mg 6-hourly had been prescribed for the baby at 12 hours, and gentamicin 7·5 mg IM 12-hourly was added at 36 hours, and the Magnapen changed to ampicillin alone. This gave a gentamicin blood level of 5·6 mg/l one hour after injection. Gentamicin was continued for a total of 14 days and ampicillin for 28 days.

The baby's condition slowly improved and she weighed 3375 g on discharge when 36 days old. She was feeding and behaving normally for a preterm neonate. The parents who were returning to Germany were strongly advised to seek developmental follow-up by a paediatrician.

Case 2. A 31-year-old Englishwoman living in an Essex village was admitted with slight vaginal bleeding. She had not recently travelled abroad. She was 29 weeks' pregnant by dates but the uterus was 36 weeks by size. Her temperature was 37·8°C, pulse 88/min, and blood pressure 130/80 mmHg. The fetal heart rate was 156/min. She was slightly flushed but had no pain. A slight brownish vaginal discharge had been present 2 weeks before. She was mildly sedated and was kept under observation.

Next day her temperature was 38°C. The fetal heart rate varied between 148 and 140/min. At midnight she had a slight bright red blood loss and a further rise in temperature to 38·8°C. Blood, urine, and a high vaginal swab were taken for culture. That night she passed a small blood clot and in the morning her temperature was 39°C and WBC $9 \cdot 3 \times 10^9$/l (85% polymorphs). Ultrasound scan excluded placenta praevia. Vaginal examination with a speculum showed an acutely inflamed, very vascular, and friable cervical polyp; a diagnosis of possible carcinoma of the pregnant cervix was made. Cytology showed only inflammatory cells. It was decided that the polyp should be removed for histology and, preparatory to this, ampicillin 500 mg 6-hourly IM for one day, followed by 500 mg 6-hourly orally with 1 g per day of probenecid was prescribed. Next day she was apyrexial but the blood culture showed *L. monocytogenes* type 1/2, so gentamicin 80 mg 8-hourly IM was added and the probenecid stopped. No growth of *Listeria* or other significant organism was obtained from the high vaginal swab or urine but these cultures were only held for 24 hours. A serum gentamicin level of 2·9 mg/l one hour after injection was obtained.

After one week's treatment, during which the patient remained apyrexial and fetal movements were vigorous, the polyp was removed. Histologically there was no evidence of malignancy but mild inflammation was present. Gram tissue stain showed no organisms, and no growth was obtained either from the polyp or from vaginal swabs taken at operation.

The next day gentamicin was stopped but ampicillin, again with probenecid, continued. Four days later the patient spontaneously delivered a healthy child. Ampicillin was discontinued next day having been given for a period of 14 days.

Serological tests showed an agglutination titre of 32 against *L. monocytogenes* on the day of delivery and again 15 days later.

The baby girl weighed 2155 g and was assessed as 37 weeks. No difficulty was experienced during delivery and she had an Apgar score of 8 to 9 at one minute and 10 at five minutes after delivery. She had no respiratory difficulty and no problems apart from low birthweight. She fed well and gained weight normally.

Listeria was not isolated from her nose, eyes, throat, or umbilicus on delivery nor was it isolated from the liquor amnii or placenta. Blood and CSF cultures were sterile. She was not given systemic antibiotics but was carefully watched for development of any respiratory or neurological signs.

Discharged at 23 days paediatric follow-up has shown normal development at the 3-month stage and should continue.

The placenta weighed 450 g and the histology showed moderate intervillous fibrin deposition and focal calcification. One area of pyogenic abscess formation in an ischaemic infarct was seen and may well reflect bacterial colonisation of an infarct. No organisms were seen.

Discussion

Only 14 cases of neonatal listeriosis have been described in the UK (Edmunds *et al.*, 1957; Barrow and Pugh, 1958; Moore and Whitmore, 1960; Harding and Brunton, 1962; Barber and Okubadejo, 1965; Coleman, 1965; Jellard and Churcher, 1965; Beck *et al.*, 1966; Scott and Henderson, 1968; Kite, 1975), and one other case is known from personal communication (D. Robson and R. N. Peel, 1976). Between 1967 and 1972, 47 cases of listerial infection in children under one year were reported to the Public Health Laboratory Service of which 14 were fatal, but the data do not say how many were neonates. Between 1972 and 1975, 24 neonatal cases were reported of whom 9 recovered and the outcome was not recorded for 6. In 1977 at least 4 out of 11 neonates died. A mortality rate of 91% for babies has been recorded in Canada (Sepp and Roy, 1963). Occasionally the child is several months old when meningitis supervenes (Wright and Macgregor, 1939; Edmunds *et al.*, 1957; Turner *et al.*, 1958).

There have been several small outbreaks in Germany (Seeliger *et al.*, 1969) and one in New Zealand (Becroft *et al.*, 1971). Infection of the mother is usually thought to occur by ingestion of contaminated food or possibly by sexual intercourse leading to either transplacental or transmembranous infection of the fetus (Robertson, 1977) from the mother's blood stream or faeces. Case 1 gives a typical antenatal history, and the bleeding polyp in Case 2 was a possible portal of entry for the organism from the vagina to the mother's blood. Hospital crossinfection of babies was a possibility in Sweden (Larsson *et al.*, 1978), but this could not be so in these two cases as the illnesses were caused by different serotypes, although the interval between them was only a few weeks.

We have found 10 cases reported in which the pregnant woman was treated (Hood, 1961; Sepp and Roy, 1963; LeGouguec *et al.*, 1971) and the diagnosis was proved by blood culture. A wide variety of antibiotics was used—such as penicillin, tetracycline, spiramycin, sulphonamide, chloramphenicol, and streptomycin, alone or in various combinations. These 10 cases resulted in 7 healthy babies, 2 infected babies, and one abortion. Our Case 2 appears to be the first to be described in Britain. Kanamycin and ampicillin in combination proved very effective in the New Zealand outbreak (Becroft *et al.*, 1971) and gentamicin and ampicillin in combination were successful in our patients.

We thank the Epidemiological Research Laboratory for data on the incidence of the disease, Mrs A. J. Macara of the Standards Laboratory of the Central Public Health Laboratory for typing the strains, the Nicholas Research Institute for measuring serum gentamicin levels, Dr R. G. M. Letcher for the histological opinions, and Mrs B. Miles for clerical assistance.

Water intoxication by the oral route in an infant

AMOS ETZIONI, ABRAHAM BENDERLEY, AND YOSEF LEVI

Department of Paediatrics A, Aba Khoushy School of Medicine, Haifa

SUMMARY Symptomatic water intoxication is common when hypo-osmolar fluids are given therapeutically, usually intravenously, but it is rare after drinking voluntarily (Wynn and Rob, 1954). We report a case of water intoxication caused by voluntary drinking in an infant.

Case report

A 10-month-old girl was admitted to hospital because of generalised convulsions which had begun an hour earlier. The child was born to a healthy mother after an uneventful pregnancy and normal delivery. Her birthweight was 3200 g and development until admission had been normal. Family history was negative and no history of excessive water requirement was noted.

On the evening before admission she developed a fever (38°C) and slight diarrhoea. The parents were advised by a doctor 'to give her a lot to drink'. The child was restless and between 01.30 and 04.00 hours she drank about 1 litre of water, without the addition of salt or sugar. Soon after 04.00 hours convulsions began. The child was brought to the emergency room. She received diazepam 2 mg IV, but after 10 minutes the convulsions recurred.

Examination on admission showed a well nourished girl weighing 9600 g. The temperature was 38°C, blood pressure 110/70 mmHg, pulse 100/min. She was lethargic and responded only to painful stimuli. Periorbital oedema was noticed.

CSF was clear with no cells, protein 20 mg/100 ml (0·2 g/l), glucose 120 mg/100 ml (6·66 mmol/l), bacterial culture—negative. Serum sugar 315 mg/100 ml (17·5 mmol/l), Ca 9 mg/100 ml (2·25 mmol/l), P 6 mg/100 ml (1·9 mmol/l), urea 25 mg/100 ml (4·15 mmol/l), K 4·3 mEq/l, Na 118 mEq/l (on repeated examination), Cl 82 mEq/l, bicarbonate 25 mEq/l. Urine electrolytes Na 25 mEq/l, K 14 mEq/l. Blood osmolality 255 mmol (normal 280 mmol). Urine osmolality 87 mmol. EEG showed generalised slowing.

She was treated with hypertonic saline (2%) 300 ml IV and after some hours she became alert and began to eat normally; the convulsions did not recur. Serum Na, 8 hours after admission was 138 mmol/l and remained normal thereafter. Her weight the next day was 9050 g; she had therefore lost 550 g. The blood glucose rapidly returned to normal with a 2 hour-postprandial value of 85 mg/100 ml (4·7 mmol/l). EEG returned to normal after a week. She was discharged and at follow-up 6 months later was doing well.

The history, laboratory data, weight loss, and clinical course left no doubt that the diagnosis was one of water intoxication.

Discussion

Involuntary water intoxication can be caused by IV administration of fluids which contain small amounts of saline. It may also follow gastric lavages or enemas, and be present in patients suffering from compulsive water drinking. Voluntary water intoxication in children is rare, and only 5 similar cases have been reported (Dugan and Holliday, 1967; Nickman *et al.*, 1968; Pickering and Hugan, 1971; Crumpacker and Kriel, 1973).

The two principal variables in maximum water tolerance (Pickering and Hugan, 1971) are the ability of the kidney to dilute, and the maximum renal tubular excretion capacity of water. The kidneys in a 3-month infant are mature as regards their ability to excrete water (Fisher *et al.*, 1963) and our 10-month-old patient could therefore be expected to excrete water as satisfactorily as an adult. When a water load is given (20 ml/kg) the expected response would be excretion of at least 75% of the water in 4 hours (De Wardener, 1973), but if the load were more than five times greater, as in our case (110 ml/kg), it is reasonable to expect that such a load would not be excreted and that water intoxication would develop.

One hypothesis for the mechanism of this syndrome is that the infant has an inappropriate secretion of antidiuretic hormone or a delayed switch-off of ADH release. This would lead to retained fluid or a delayed excretion of the water load. As most infants are 'sick' before they are given large, 'voluntary' loads of fluid, one might suggest such a mechanism. Measurements of ADH secretion have not been made in such infants, but the low osmolality of the urine in our patient is against such an hypothesis because, if secretion of ADH is inappropriate, urine osmolality must be high. The hyperglycaemia in our patient may have been caused by the convulsions (Rutter and Smales, 1977).

Symptoms of hyponatraemia usually begin when serum Na <120 mEq/l (Wynn and Rob, 1954), but they will begin sooner if the hyponatraemia develops rapidly, as in our child who probably became hyponatraemic in less than 4 hours.

When treating with hypertonic saline, it is not known how rapidly levels of plasma Na can safely be raised in patients with acute hyponatraemia, nor how long it takes for acute hyponatraemia to cause permanent brain damage. Apart from hypertonic saline (usually 3%) and water restriction, no other form of treatment has proved to be effective (Crumpacker and Kriel, 1973).

This case once more emphasises the need for clarity when prescribing; the laconic order 'to give a lot to drink' allows room for much ambiguity. The physician should be specific with regard to the kind of fluid to be given, its amount, and frequency of administration.

Copper deficiency in a low birthweight infant

P. YUEN, H. J. LIN, AND J. H. HUTCHISON

University Departments of Paediatrics and Pathology, Queen Mary Hospital, Hong Kong

SUMMARY Copper deficiency is reported in an infant of very low birthweight. It was characterised by extensive bone changes, severe neutropenia, and hypocupraemia. These manifestations could have been missed but for an intercurrent pneumonia which led to an *x*-ray of the chest.

Low birthweight infants go into negative nitrogen balance from birth and there may also be substantial losses of trace elements (Shaw, 1973). Absorption of nutrients may also be poor. It is surprising, therefore, that there have been so few reports of copper deficiency in low birthweight infants (Al-Rashid and Spangler, 1971; Griscom *et al.*, 1971; Ashkenazi *et al.*, 1973; Sann *et al.*, 1978) and it is possible that some cases go unrecognised.

Case report

A Chinese baby, son of a 28-year unmarried hostess at a dance hall, was born spontaneously in the hospital casualty department at 28 weeks' gestation on 24 August 1977. Birthweight 970 g; length 39 cm; head circumference 26 cm. The clinical and radiological features of idiopathic RDS rapidly developed. The infant was nursed in an incubator in 60% O_2, an umbilical artery was catheterised for blood–gas studies, and IV 10% dextrose was given at a rate of 3 ml/hour. Apnoeic attacks necessitated the use of CPAP on 25 August and IV aminophylline was given 1·5 mg six-hourly. Pa_{O_2} varied between 47 and 115 mmHg (6·2 and 15·3 kPa). Metabolic acidosis was corrected with sodium bicarbonate. Parenteral feeding with Aminofusin, dextrose, and Intralipid was started on 26 August. CPAP was stopped on 30 August, and the ambient O_2 concentration gradually reduced. An attempt at nasogastric feeding on 31 August produced blood from the gastric aspirate and Hb fell to 10 g/dl, and then rose to 15 g/dl after a transfusion of 25 ml fresh blood. Parenteral feeding was discontinued on 20 September when the infant's full caloric requirements were being given in the form of Nan (Nestlé) by nasogastric tube. Hb was 11·5 g/dl. On 1 October proprietary ferrous sulphate and multivitamin preparations were started orally. However, on 4 October Hb was 7·6 g/dl; WBC 45·1 × 10^9/l; neutrophils 31%; lymphocytes 69%; platelets 645 × 10^9/l; reticulocytes 4·8%. Films showed 12 nucleated RBC/100 WBC. On the suspicion of vitamin E deficiency (Willoughby, 1977) IM tocopherol 100 mg daily was given for 4 days. Unfortunately, the infant developed bronchopneumonia (treated with IV gentamicin and ampicillin) and on 17 October Hb was 6·3 g/dl; reticulocytes 8·7%. A further 4-day course of tocopherol was given and on 10 November Hb was 11·3 g/dl; reticulocytes 2·6%. The infant was discharged home on 22 November on Nan 75 ml three-hourly × 8, plus iron and vitamin supplements. Weight 2·33 kg; head circumference 32·5 cm.

The baby was readmitted on 13 December extremely ill and convulsing with bronchopneumonia. Weight 3·0 kg. Respirations 60/min. Blood pH 7·03; Pa_{O_2} 73 mmHg (9·7 kPa); Pa_{CO_2} 94 mmHg (12·5 kPa); base excess—7·5 mmol/l. Serum Na 132 mmol/l; K 5·8 mmol/l; Ca 2·4 mmol/l (9·6 mg/100 ml); P 2·38 mmol/l (7·4 mg/100 ml); Mg 1·0 mmol/l (2·4 mg/100 ml). Hb 10·2 g/dl; WBC 20·3 × 10^9/l; neutrophils 26%; lymphocytes 67%; monocytes 7%; reticulocytes 4·6%. CSF normal. There was a good response to cephradine given IV combined with nursing in 40% O_2. However, a repeat chest *x*-ray on 21 December showed widening of the anterior rib ends, subperiosteal reaction, and fractures of the right 6th, 7th, and 8th ribs and of the left 5th, 6th, 7th, and 8th ribs.

A skeletal survey showed diaphyseal subperiosteal new bone formation with cupping and flaring of the metaphyses and severe osteoporosis. There were fractures of the lower ends of the left radius and right ulna (Figure). Repeat blood tests showed serum Ca 2·1 mmol/l (8·4 mg/100 ml); P 2·94 mmol/l (9·1 mg/100 ml); alkaline phosphatase 610 μmol/min per litre (Chinese adults 35–115). VDRL negative. On 19 January 1978 serum Cu was 0·7 μmol/l (4·5 mg/100 ml) (normal 11–25), and serum caeruloplasmin was barely detectable (normal 62–108 μmol/min per litre). Hb was 11·9 g/dl; WBC 7·3 × 10^9/l; neutrophils 1%; lymphocytes 90%; monocytes 8%; eosinophils 1%; serum Fe 8 μmol/l (44·7 μg/100 ml); TIBC 51 μmol/l (285 μg/100 ml). On 25 February, when the infant had been on cereals in addition to the milk formula for 52 days, serum Cu was 2·0 μmol/l (12·7 μg/100 ml); caeruloplasmin 10 μmol/min per litre; plasma ascorbate 94·2 μmol/l (1·6 mg/100 ml); serum zinc 9·2 μmol/l (60·1 μg/100 ml) (Chinese adult range 15·7 ± 2·75 μmol/l). *X*-rays taken on 1 March already showed early healing of bone lesions but the infant was started on 0·6 ml of 0·5% copper sulphate solution daily. On 14 March serum Cu was 10 μmol/l (63·7 μg/100 ml); caeruloplasmin 43 μmol/min per litre. Hb was 12·4 g/dl; WBC 15·6 × 10^9/l; neutrophils 47%; lymphocytes 51%; monocytes 1%; eosinophils 1%; reticulocytes 2·6%; platelets 339 × 10^9/l. Copper supplements were stopped on 22 March when serum Cu was 22 μmol/l (140 μg/100 ml); caeruloplasmin 65 μmol/ min per litre. *X*-ray on 29 March showed almost complete healing of bone lesions apart from residual subperiosteal reaction in both femora, although bone-age was only 3 months. The infant went home on 18 May, weight 4·8 kg, on feeds of Cow and Gate Babymilk Plus and mixed feeding. He was still unable to sit unsupported or to roll over from the supine to the prone posture, but in the prone position he could lift his head and chest off the table and he made attempts to grasp objects. Unfortunately his home environment is unlikely to encourage much stimulation.

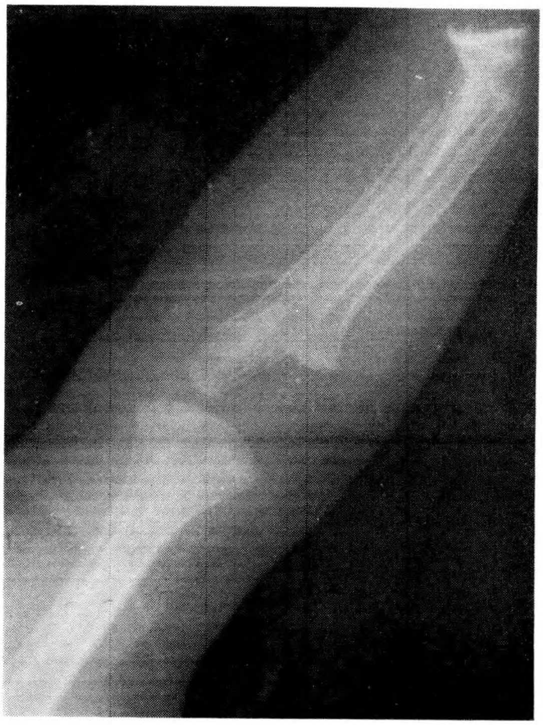

Figure *X-ray at age 4 months showing subperiosteal reaction, osteoporosis, flaring and cupping of metaphyses, and fracture of lower end of radius.*

Discussion

The diagnosis of copper deficiency in this case is based upon the characteristic bone changes, severe neutropenia, and extremely low serum copper and caeruloplasmin levels. Anaemia is common in copper deficiency but was absent in our patient. When the bone changes were first discovered our initial suspicion was rickets. Indeed, this has been reported in association with copper deficiency in a low birthweight infant (Sann *et al.*, 1978). However, the high serum phosphate level made this diagnosis unlikely, particularly as the infant had been receiving a calculated daily intake of at least 10 μg vitamin D. We have not seen such severe subperiosteal new bone formation in rickets but measurements of plasma 25-OHD$_3$ or iPTH were not available to us. There was no evidence of nonaccidental injury and the long bone changes were incompatible with this diagnosis. If this infant had not been readmitted to hospital with pneumonia the diagnosis would have been missed because even after finding extensive bone changes on *x*-rays there was no clinically obvious beading of the ribs or epiphyseal enlargement, and it is probable that spontaneous healing would have followed the introduction of mixed feeding. On the other hand, a neutropenia of 1% must have greatly reduced the infant's resistance to infection.

Copper deficiency has been reported in older infants after prolonged total parenteral nutrition (Karpel and Peden, 1972; Heller *et al.*, 1978) as well as in very low birthweight infants. In our patient parenteral nutrition was only total for 6 out of 26 days, and the extreme prematurity and low birthweight were likely to be more important factors leading to copper deficiency.

We thank Dr L. Y. Y. Fong for the serum zinc analysis.

Pulmonary candidiasis in cystic fibrosis

B. M. JENNER, L. I. LANDAU, AND P. D. PHELAN

Royal Children's Hospital, Melbourne, Australia

SUMMARY A child with cystic fibrosis and asthma developed pulmonary candidiasis. Predisposing factors in this patient were prolonged antibiotic therapy, high-dose corticosteroids, and intravenous catherisation. A diagnosis was made by lung puncture and confirmed by rapid response to 5-fluorocytosine.

Pulmonary candidiasis is an invasion of viable lung tissue by *Candida* species. It has long been known that this occurs in patients with impaired host resistance—such as those with Hodgkin's disease or leukaemia, and those on cytotoxic therapy. In 1844 Bennett commented: 'it is indicative of great depression of the vital powers and impairment of the nutritive functions of the economy' (Winner and Hurley, 1966).

Candida colonisation is seen in the tracheobronchial tree of children with cystic fibrosis on long-term antibiotics. Pulmonary candidiasis, however, has not been reported in such children.

This is a report of a child with cystic fibrosis and asthma requiring corticosteroids, who developed pulmonary candidiasis and responded to treatment with 5-fluorocytosine.

Case report

A 6½-year-old girl had cystic fibrosis diagnosed in the first year of life and associated bronchial asthma. She was initially well maintained on standard antibiotic and physical therapy for cystic fibrosis lung disease, with intermittent bronchodilator treatment for the asthma.

At age 5 years she required continuous bronchodilators and, subsequently, three intermittent courses of corticosteroids to control the wheeze. At 6 years more prolonged courses of high-dose prednisolone were necessary to control quite severe airways obstruction but these were reduced to a maintenance dose of 4 mg daily. During a course of high-dose prednisolone for an acute exacerbation of airways obstruction she became increasingly lethargic, lost weight, and developed a fever which reached 39°C daily. She developed rapid shallow breathing with fine inspiratory crepitations. Chest *x*-rays showed increased reticulonodular markings (Figure).

Intravenous cloxacillin and gentamicin, and later chloramphenicol and carbenicillin, were given for nearly 4 weeks without response. On several occasions sputum cultures grew *Escherichia coli*, *Streptococcus* species, *Haemophilus influenzae*, and *Achromobacter* species, but moderate to profuse growth of *Candida* species, not *C. albicans*, was always present. Multiple blood cultures were negative. Immune function tests were normal. Tuberculosis, autoimmune disease, and sepsis elsewhere were excluded.

A lung puncture was performed with instillation of 2 ml saline into the lung and aspiration of alveolar fluid. This fluid was smeared and cultured. A pure growth of *Candida* species, not *C. albicans*, was obtained.

She was started on 5-flurocytosine orally; within

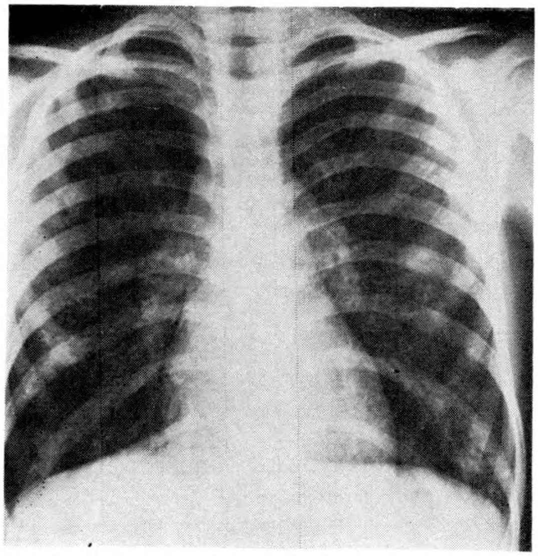

Figure *Chest x-ray at the onset of the febrile illness. The lungs are overinflated. There is patchy nodular consolidation throughout both lung fields with prominent peripheral parenchymal opacities. The hilar vessels are prominent.*

4 days her condition had improved, her appetite had returned, and she became ambulant for the first time in 2 months. She was afebrile within 10 days. Chest *x*-ray one month later showed significant clearing. 5-Fluorocytosine was continued for 6 weeks. She developed mild diarrhoea during the last week of this regimen.

Discussion

The rarity of pulmonary candidiasis is attributed to a natural resistance of columnar epithelium to invasion by the *Candida*, which is particularly prone to attack stratified epithelium. Pulmonary candidiasis occurs when there are impaired host defence mechanisms. It has been known to present as severe tracheobronchitis, bronchopneumonia, or pulmonary abcess. Although not usually seen in cystic fibrosis, predisposing factors in this child were a debilitating disease, prolonged antibiotic and corticosteroid therapy, and prolonged intravenous catheterisation (Hurley *et al.*, 1975).

Establishing a diagnosis can be difficult as was shown in this child. The clinical findings of tachypnoea and fever, with crepitations and rhonchi in the chest, are nonspecific and the radiological findings are not characteristic (Goldstein and Hoeprich, 1972). Candidaemia may not be associated with tissue invasion and, on the other hand, a negative blood culture does not exclude invasive candidiasis (Mirsky and Cuttner, 1972). Sputum culture does not indicate invasion. The most reliable method of diagnosis is demonstration of the fungus in lung tissue histologically. Lung puncture is next best, but even so, *Candida* can be cultured from lung fluid without invasion (Klein, 1969; Bandt *et al.*, 1972).

Treatment of pulmonary candidiasis with 5-fluorocytosine appears to be effective (Kohlschütter and Pelet, 1974), There are few side effects with this drug, those described being predominantly anorexia, nausea, vomiting, and diarrhoea. There have been some reports of haemopoietic depression as well as renal and hepatic toxicity. *Candida* has been noted to develop resistance to 5-fluorocytosine. Amphotericin B has also been used for the treatment of candidiasis but it was not used in this instance because of its known toxicity. The combination of these two drugs in extremely ill patients has been recommended (Montgomerie *et al.*, 1975).

Pulmonary candidiasis, although a rare complication, should be considered in children with cystic fibrosis who develop a febrile illness not responding to antibiotics. This complication may become an increasing problem with the use of corticosteroids and long-term intravenous catheters in a small group of children with cystic fibrosis in whom this type of treatment appears warranted.

Effective treatment for rhinopulmonary mucormycosis in a boy with leukaemia

O. B. EDEN AND J. SANTOS

Children's Hospital at Stanford and Department of Paediatrics, Stanford University Medical Centre

SUMMARY Lymphoblastic leukaemia in a 3-year-old child was complicated by rhinopulmonary mucormycosis. This was successfully treated by surgical resection of the nasal mass, pulmonary lobectomy, combined with amphotericin.

Effective treatment of childhood lymphoblastic leukaemia has been associated with an increased incidence of atypical infections (Hughes, 1971; Krick and Remington, 1976), including phycomycosis (Harris, 1955; Mirsky and Cuttner, 1972; Myer *et al.*, 1972). Successful management of rhinopulmonary mucormycosis in childhood malignancy has not been reported.

Case history

In July 1971, a 3½-year-old white boy with a leucocyte count of 7·7 × 10^9/l was diagnosed as having acute lymphoblastic leukaemia (ALL). Chemotherapy was begun with daily prednisolone (40 mg/m^2) and weekly vincristine (1·5 mg/m^2). Once in remission at 4 weeks, central nervous system prophylaxis was given (2000 rads to the craniospinal axis over 13 days with weekly injections × 2 of intrathecal methotrexate 0·5 mg/kg). Maintenance was with daily 6-mercaptopurine (50 mg/m^2), weekly oral methotrexate (20 mg/m^2), and cyclophosphamide (200 mg/m^2), with vincristine and prednisolone pulses every 3 months.

In May 1974 the child developed a right hemiparesis and a left 3rd and right 6th and 7th cranial nerve palsies. Fundoscopy was normal and there was no meningismus. Investigations identified a 2–3 cm mass to the left of the midline at midbrain level, deviating the 3rd ventricle to the right. Lumbar thecal pressure was normal with CSF glucose 65 mg/100 ml (3·6 mmol/l) and protein 38 mg/100 ml (0·38 g/l), with no cells. Abnormal vascularity was confirmed on carotid arteriography. Biopsy was deferred because of the lesion site but a trial of irradiation to a total dose of 4000 rads (2500 rads to whole brain and 1500 rads to midbrain) over 18 days produced slight improvement in limb power only. This was considered to suggest a new tumour, not a leukaemic or encephalopathic lesion. Computerised axial tomography (CAT) showed an increase in tumour size.

Leukaemic therapy was stopped and oral 1–(2-chloroethyl)–3 cyclohexyl–1 nitroso–urea (CCNU) began (100 mg/m^2) orally every 6 weeks. Between the first two dosages the tumour enlarged by a further 20% with neovascularity, but the child remained clinically well at school. Neither bone marrow nor CSF showed evidence of leukaemic relapse until April 1976 (22 months after stopping antileukaemic treatment) when he developed a left-sided bronchopneumonia coincident with haematological relapse. Leukaemic therapy was restarted and CCNU stopped. Remission was again achieved after one month. CAT scan showed calcification without further enlargement of the midbrain lesion. One month later (2 years after the development of hemiparesis) he had fever and mucopurulent nasal discharge, with bilateral opacified ethmoid and maxillary sinuses, left lower lobe pulmonary infiltrates, and the left hemidiaphragm was raised. *Staphylococcus aureus* was initially cultured from the nose but the condition did not improve with treatment on methicillin. Nasal debridement showed a large necrotic polypoid mass containing irregular broad fungal hyphae, mostly nonseptated, suggestive of mucormycosis (Fig. 1). Cultures were negative. The mass had occupied the nares, right maxillary antrum, and ethmoid sinus, causing septal perforation. After a test dose (1 mg), amphotericin in a dose of 0·25 mg/kg per day was begun and increased by 0·25 mg/kg per day to a maximum dose of 1 mg/kg per day. Each dose was given in 250 ml 5% dextrose with 250 units heparin and 25 mg hydrocortisone over 6 hours. Periodically, raised blood urea, nitrogen, and creatinine levels necessitated dosage being interrupted for a maximum of 2 days. Altogether 1212 mg was administered over 7 weeks. The nose progressively improved but despite intensive physiotherapy the lung infiltration worsened (Fig. 2). Needle aspiration, bronchoscopy, and left lower lobectomy followed. On each occasion necrotic material containing occasional branching nonseptated hyphae was obtained. All fungal cultures however were negative. Postoperative recovery was complicated by wound haematomata but no infection. No further amphotericin was given.

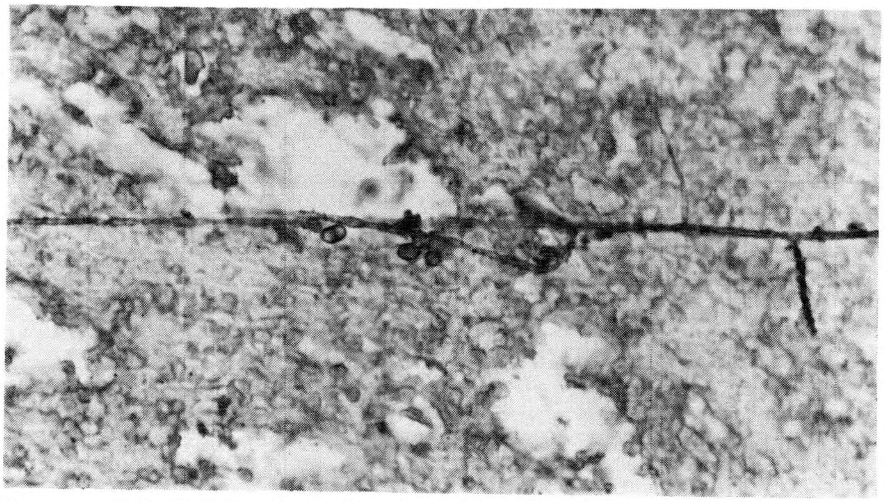

Fig. 1 *Fungal hyphae identified in debris from the nares.*

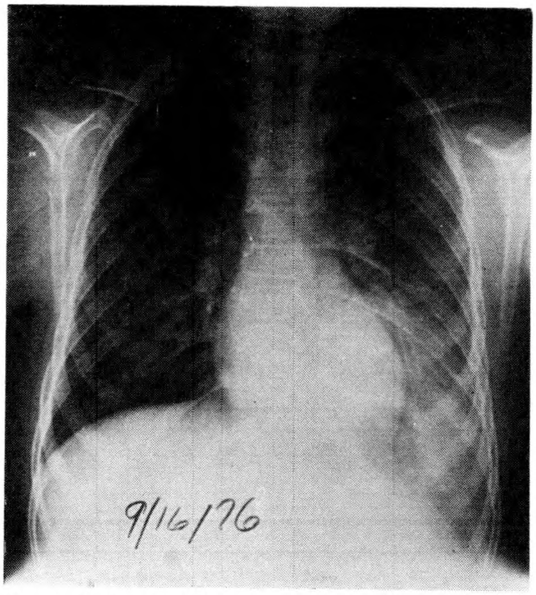

Fig. 2 *Left lower lobe pneumonic consolidation.*

To date (2 years 7 months after diagnosis of rhinopulmonary mucormycosis) the child remains well on antileukaemic chemotherapy in complete remission, but he has a persistent thalamic tumour showing contrast enhancement but no increase in size. He has no rhinorrhoea or evidence of active pulmonary disease despite a persistently paralysed left hemidiaphragm and a right hemiparesis. He attends school regularly and plays football.

Discussion

Nearly 3 years after the diagnosis of leukaemia this boy developed an intracerebral lesion and after 2 further years rhinopulmonary mucormycosis. That these two occurrences were related had to be considered. He has shown no CNS symptom progression while investigations gave no evidence of meningeal disease but showed neovascularity with late calcification. Without histology the exact nature of the mass is uncertain. Retrospectively, we have to consider rhinocerebral mucormycosis which can occur in children (Harris, 1955; McBride *et al.*, 1960; Baker, 1962). The usual features of systemic infection of ophthalmoplegia, uncontrolled diabetes insipidus, and meningoencephalitis were all absent (Harris, 1955; McBride *et al.*, 1960). Rapidly fatal isolated cerebral mucormycosis has been reported (Myer *et al.*, 1972). Our patient had the lesion for at least 2 years without antifungal therapy but with continuing chemotherapy. Mucormycosis is a very aggressive infection and if untreated it will progress to death within a matter of weeks (Harris, 1955; McBride *et al.*, 1960). Mucor hyphae were seen in nasal and lung tissue. The incidence of mycotic infections in leukaemic patients has progressively risen and now up to 30% of significant infections are of such a nature (Mirsky and Cuttner, 1972; Myer *et al.*, 1972; Krick and Remington, 1976). Aspergillus and the phycomycetes are also showing a differential increase compared with Candida (Mirsky and Cuttner, 1972; Myer *et al.*, 1972; Krick and Remington, 1976).

Phycomycosis normally originates in the nose and paranasal sinuses and characteristically invades the walls and lumen of blood vessels. In leukaemic patients it usually also invades lung and sometimes becomes disseminated (Mirsky and Cuttner, 1972; Myer *et al.*, 1972). Any lung lobe can be affected and infarction is common (Medoff and Kobayashi, 1972). The organism is difficult to recover and grow in culture. Frequently the diagnosis is made at necropsy (Krick and Remington, 1976). It is not a common human saprophyte and therefore the presence of mucor hyphae on any biopsy smear must be taken as strong evidence of infection (Myer *et al.*, 1972; Krick and Remington, 1976). This is especially so in a febrile leukaemic patient with a persistent and/or progressive antibiotic resistant pneumonia.

Our patient is thought to be the first child with leukaemia to be successfully treated with amphotericin and surgical resection for extensive rhinopulmonary mucormycosis. We stress the need for aggressive diagnostic procedures, including debridement and resection, in conjunction with adequate amphotericin if this diagnosis is suspected.

We acknowledge the help of Dr A. Yeager and Dr T. Long in preparing this manuscript.

Neonatal aspergillosis accompanying fulminant necrotising enterocolitis

HENRY H. MANGURTEN AND BALBINO FERNANDEZ

Departments of Paediatrics (Section of Neonatology) and Pathology, Lutheran General Hospital, Illinois

SUMMARY A preterm infant developed fulminant necrotising enterocolitis, subsequently resulting in death. Necropsy examination showed diffuse aspergillosis. Reports are reviewed, and possible mechanisms resulting in *Aspergillus* infection in this infant are discussed.

Disseminated aspergillosis in all age groups is almost always associated with an underlying chronic illness or other predisposing factors—such as prolonged administration of antibiotics or corticosteroids (Zimmerman, 1955; Luke *et al.*, 1963; Riley, 1972). The *Aspergillus* is a fungus which rarely causes disease in humans. In children, particularly during the neonatal period, aspergillosis is exceedingly rare (Allan and Andersen, 1960; Luke *et al.*, 1963). We recently unexpectedly discovered diffuse aspergillosis in a preterm infant dying from fulminant necrotising enterocolitis (NEC). We can find only five reports (see Table) of neonatal aspergillosis (Zimmerman, 1955; Akkoyunlu and Yucel, 1957; Allan and Andersen, 1960; Matturri and Fasolis, 1962; Luke *et al.*, 1963). We can find no previous report of this organism in association with NEC. Accordingly we describe our findings.

Case report

A 950-g boy was born by caesarean section to a 25-year-old primigravid mother after 31 weeks' gestation. Membranes ruptured spontaneously 32 days before delivery. The mother was observed in the hospital for 4 days and discharged home to rest in bed. She was readmitted 2 weeks before delivery because of peptic ulcer disease. She was treated with diazepam, diphenoxylate-hydrochloride with atropine sulphate, trimethobenzamide hydrochloride, acetaminophen, chlordiazepoxide hydrochloride with clidinium bromide, and various antacids. In addition she was given vitamins, secobarbital sodium, diphenhydramine hydrochloride, and iron dextran injection. A cholecystogram was normal. A lecithin/sphinogomyelin (L/S) ratio on amniotic

*Infection related to neonatal problem; infant never left hospital after birth.

fluid collected vaginally 10 days before delivery was 2·3/1. Vaginal bleeding and vague uterine contractions developed 2 days before delivery. Ultrasound examination was unrevealing. Several hours before delivery the maternal temperature rose to 37·5°C, associated with increasing abdominal pain and increase in fetal heart rate. In view of the mature L/S ratio and increasing hazard of infection to mother and fetus, a primary caesarean section was performed under general anaesthesia. Oligohydramnios was noted at delivery. Apgar scores were 7 at one and five minutes. The infant was taken to the high-risk nursery, pink and crying, with mild retractions. Examination of the placenta showed massive subchorionic fibrin deposition.

Physical examination showed a preterm infant who was pink, active, and responsive, with no respiratory distress. The head appeared disproportionately large for the body. Air exchange was fair bilaterally. The skin was dry and peeling, with diminished subcutaneous tissue. Neurological examination showed a fairly good cry and suck, normal tone, and no reaction to Moro's test.

The infant was given maintenance fluids by peripheral vein. Cultures of peripheral blood, urine, and stool were subsequently reported to be negative. At 10 hours nasogastric feedings were started. The first 6 days of life were relatively uneventful, and the infant tolerated gradual formula increases well. On day 7 he developed lethargy, abdominal distention, absent bowel sounds, poor feeding, increasing gastric residue, and grossly bloody stools. Roentgenograms showed evidence of pneumatosis coli. Repeat cultures were taken of blood, urine, and CSF, and ampicillin and gentamicin were started. Feedings were stopped, and nasogastric suctioning was initiated. All repeat cultures were again negative. Frequent serial abdominal *x*-rays showed no change. However, the condition of the infant continued to deteriorate, with bloody stools and progressive apnoea and bradycardia requiring frequent vigorous stimulation. On day 9 he became cyanotic and unresponsive, requiring intubation and respiratory assistance.

On day 13 an upright roentgenogram of the abdomen showed free air under the diaphragm. Platelet count was 3·0 × 10^9/l, and partial thromboplastin time and prothrombin time were prolonged. Heparin and platelets were given. Exploratory laparotomy showed a recent perforation of the caecum; about 150 ml of serosanguineous fluid was obtained during surgery. Because of the moribund condition of the patient, a loop ileostomy was placed. Cultures of peritoneal fluid subsequently showed an unidentified anaerobe. Accordingly, clindamycin was started, and ampicillin was stopped.

After surgery the infant developed renal failure, followed shortly by rising serum potassium levels. Blood glucose became very labile, ranging from 11 to 1011 mg/100 ml (0·6 to 0·056 mmol/l). On the last day of life, he developed arrhythmias compatible with hyperkalaemia. His condition gradually deteriorated and he died on day 16. Multiple necropsy cultures showed no growth in cardiac blood or CSF, nor was there growth in either lung or in the tip of endotracheal tube. *Clostridium* species was recovered from rectum, ileostomy site, and peritoneal fluid; *Aspergillus* was recovered from the ileostomy site and peritoneal fluid.

Necropsy findings

Gross description. There were extensive areas of ecchymoses with superficial ulcers. The abdominal cavity contained a scanty amount of dark red fluid. The intestinal loops were distended and dark purple. There was an area of perforation at the base of the appendix; two areas of perforation were present in the descending colon. The liver was enlarged, extending 4 cm below the right costal margin. There were large erosions of the mucosa of the stomach. The brain showed extensive subarachnoid haemorrhage of the left temporal lobe and cerebellum.

Microscopical description (Figs 1 and 2). There was diffuse necrosis of the wall of the small intestine and colon with abundant colonies of *Aspergillus* infiltrating the wall. Similar findings were observed at the site of the gastric erosions. There was a diffuse bronchopneumonia with extensive infiltrates of *Aspergillus*. The liver showed areas of necrosis with abundant colonies of *Aspergillus*.

Discussion

Neonatal NEC has been described in detail (Pochaczevsky and Kassner, 1971; Stevenson *et al.*, 1971; Frantz *et al.*, 1975). Bacterial infection with resultant peritonitis and septicaemia is a recognised complication of the disease (Hopkins *et al.*, 1970). Infection caused by bacteria or viruses has been considered as one of the aetiological factors, although one report did not give any bacterial, viral, or fungal cause of NEC (Virnig and Reynolds, 1974). Levin and Isaacson (1960) reported a preterm infant who died on day 12 of NEC with resultant perforation and peritonitis; necropsy examination showed fungal hyphae within bowel lumen, wall, and serosa near the site of perforation. Although cultures were not taken, the appearance of the organism was thought to be consistent with mucormycosis. We can find no other report that indicates an association between fungal infection and NEC.

The *Aspergillus* species is common and rarely causes disease in humans. The organism may be encountered as a contaminant of laboratory cultures. The presence of *Aspergillus* in multiple sites in this infant—for example stomach, small intestine, liver, and lungs—is strong evidence against laboratory contamination. The patient reported here had a fulminant variety of NEC, with many severe complications (intestinal perforation, peritonitis, possible anaerobic sepsis, disseminated intravascular coagulation, renal failure). This overwhelming form of NEC in association with prematurity possibly compromised him immunologically. The *Aspergillus* organism is a known 'opportunist'; the chronically ill condition of this preterm infant in association with a severely compromised gastrointestinal tract and broad-spectrum antibiotic therapy resulted in

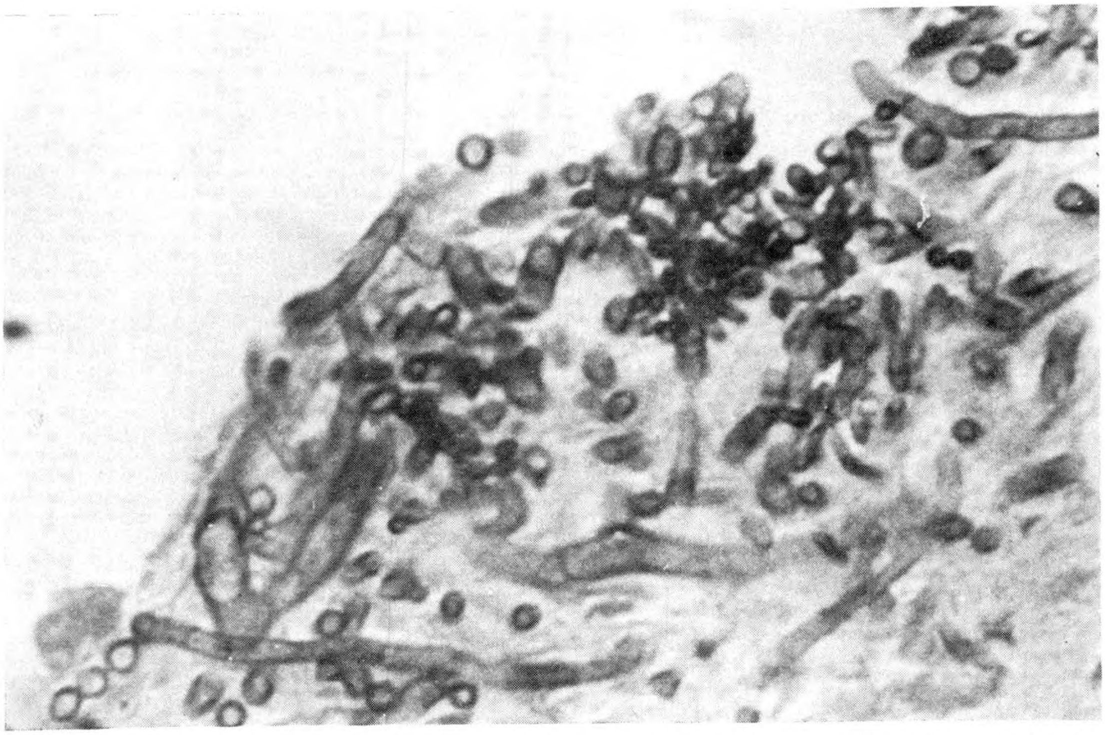

Fig. 1 *Section of the ulcerated mucosa of small intestine with abundant growth of Aspergillus. (Haematoxylin and eosin, ×400).*

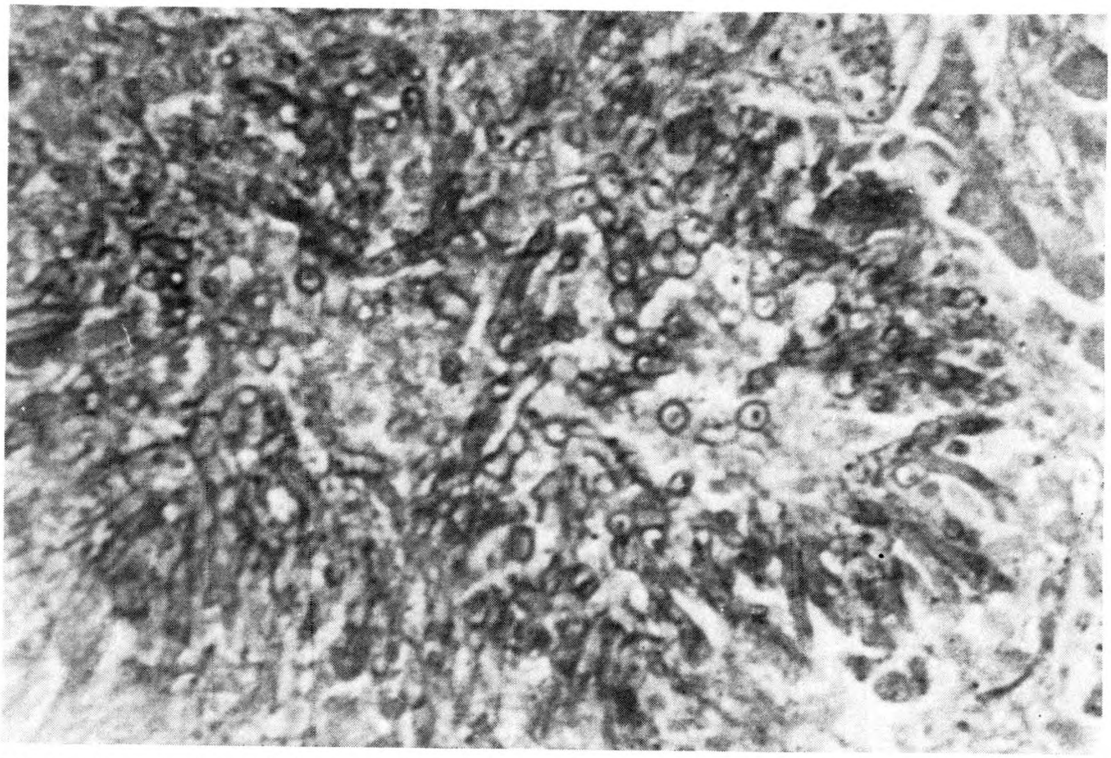

Fig. 2 *Mass of hyphae in the liver parenchyma with extensive necrosis of liver cells. (Haematoxylin and eosin, ×400).*

an ideal environment for *Aspergillus*. The fungus probably invaded the wall of the ulcerated stomach and necrotic intestine, extending via the portal circulation to the liver and subsequently via the blood stream to the lungs.

Simple method for stabilising umbilical catheters

Sir,

We were interested in the letter from Gatrad (*Archives*, 1979, **54**, 166). For the last 2 years we have used a method for stabilising umbilical catheters that has almost eliminated the problem of accidental dislodgement.

The umbilical cord is cut approximately 2 cm from the base, sterilised with povidone-iodine solution, and the lumen of the umbilical artery carefully dilated with fine forceps. A fluid-filled 5 FG catheter is then inserted and advanced in the usual manner. Once positioned, there should be free flow of arterial blood from the catheter. Position of catheter tip at the level of the 3rd or 4th lumbar vertebra is ascertained by *x*-ray. A 4–0 silk purse string suture is passed around the artery containing the catheter (not the entire base of the cord) and tied. One end of this suture is passed through the skin at the base of the cord. This is tied and cut so as to leave about 4–5 cm of free ends of the suture. These lengths of suture are then taped securely to the catheter just above its entry into the artery with standard 2.5 cm adhesive tape. A length of umbilical cord tape is passed around the waist of the infant and tied loosely. This loop is taped securely to the catheter 5–6 cm above the previous piece of tape, thus preventing the catheter from being dislodged should traction be applied to it during *x*-rays, routine care, or weighing of the infant. Povidone-iodine solution is applied twice daily to the cord and to the place at which the catheter is inserted until it is removed. The Figure shows this method of stabilisation in a low birthweight infant.

Techniques of catheterisation of umbilical vessels have been well described. Most methods of stabilisation combine purse string suturing around the catheter with taping of the catheter to the skin of the infant with or without a covering gauze dressing. This can lead to the catheter slipping through the purse string suture and to trauma to large areas of skin in low birthweight infants. Such areas subsequently serve as sites of increased fluid and protein loss and can be potential portals of entry for infection. Even paper tape may denude the skin of the small premature baby during the first 3 days of life.

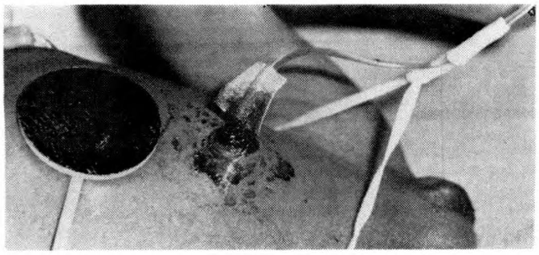

Figure *Method of stabilising umbilical catheter.*

Our technique, besides making accidental dislodgement of the catheter unlikely, additionally allows the umbilical cord to remain dry, and reduces the risk of colonisation with hospital-acquired organisms.

Chloramphenicol and phenobarbitone —a drug interaction

Sir,

I read with interest the Short Report by Bloxham *et al.* (*Archives*, 1979, **54**, 76). The authors are mistaken in their belief that the interaction between these drugs has not been specifically reported in man. Windorfer and Pringsheim (1977) reported that premature and newborn babies (n = 20) who received phenobarbitone in addition to chloramphenicol and penicillin had lower levels of chloramphenicol than groups of comparable babies who received chloramphenicol alone (n = 29) or chloramphenicol and penicillin combined (n = 35).

The Short Report draws attention to the problem of drug interactions, and two points are worthy of mention. Chloramphenicol is known to inhibit the hepatic microsomal enzyme system (Adams *et al.*, 1977) and it causes a reduction in phenobarbitone clearance (Koup *et al.*, 1978) and raises the levels of phenytoin and other drugs (Christensen and Skovsted, 1969). It would therefore have been particularly interesting to have seen the trend in serial phenobarbitone concentrations in the two cases cited by Bloxham *et al.* Sodium valproate may offer no advantage, as although it appears to have little or no enzyme-inducing properties, it may in fact inhibit the microsomal enzyme system and this is presumably one mechanism by which an increase in phenobarbitone, phenytoin, and primidone concentration occurs when these drugs are used in combination with sodium valproate (Windorfer *et al.*, 1975; Vajda *et al.*, 1976).

It is imperative that all possible drug-drug interactions are considered when contemplating giving a combination of drugs. The importance of drug level monitoring, especially in these circumstances, is worth emphasising.

George W. Rylance
Department of Child Health,
University of Dundee,
Ninewells Hospital,
Dundee DD1 9SY

Drs Durbin and Winterborn comment:

We are pleased that Dr Rylance agrees with the aim of our report which was to stress the need for regular monitoring of blood levels when chloramphenicol is used in combination with other drugs, particularly enzyme-inducing anticonvulsants. We did not measure serial phenobarbitone levels but neither patient showed evidence of toxicity in the form of unduly prolonged or increasing drowsiness. Any possible advantage of sodium valproate remains to be established by direct observation, but the evidence cited by Dr Rylance suggests that by inhibiting degradation, sodium valproate may actually increase the antibacterial activity of a given dose of chloramphenicol.

We thank Dr Rylance for drawing our attention to the report by Windorfer and Pringsheim (1977) which stated that addition of phenobarbitone to the *combination* (our italics) of chloramphenicol and penicillin reduced the serum chloramphenicol concentration in the neonate but not in infants or older children. We do not agree that their report invalidates our claim to the first specific report of the interaction between chloramphenicol and phenobarbitone in man. Windorfer and Pringsheim used a photometric assay which fails to distinguish between active chloramphenicol and its breakdown products. Their finding of increased chloramphenicol levels in neonates and infants treated with penicillin and chloramphenicol can be attributed at least in part to penicillin-induced renal retention of the breakdown products (Windorfer, 1972). It is therefore difficult to interpret their finding in neonates and infants that serum chloramphenicol concentration did not differ significantly between patients given chloramphenicol alone and those given the combination of chloramphenicol + penicillin + phenobarbitone. In the only group they were able to assess, they found no significant difference in the serum chloramphenicol levels of infants given chloramphenicol alone (n = 45) and of those given chloramphenicol + phenobarbitone (n = 40). The contradiction between their findings and ours may be explained by the relatively insensitive method of their study. They compared single measurements of serum (chloramphenicol + breakdown products) to the weight-related dose of chloramphenicol in children of different ages given different combinations of drugs, without allowing for the earlier duration of treatment. We suggest that Windorfer and Pringsheim would have demonstrated a significant effect of phenobarbitone on the serum level of biologically active chloramphenicol if, as we did, they had used a bioassay to measure the serum levels serially. In the event they did not.

Henoch-Schönlein syndrome after chickenpox

Sir,

On the basis that one swallow does not make a summer, readers may not have paid too much attention to the letter from Halle (*Archives*, 1979, **54**, 166) suggesting that it was the first account of Henoch-Schönlein syndrome after chickenpox. However, the association has been reported before. In a series of 88 children with Henoch-Schönlein nephritis (Meadow *et al.*, 1972) we found that 5 children had had a specific infectious fever in the 6 weeks preceding onset of purpura. These illnesses were chickenpox in 2 children, and measles, rubella, and scarlatina in the other 3. The onset of chickenpox had been 5 weeks in one child and 10 days in the other before the onset of purpura.

Furthermore Pedersen and Petersen (1975) reported a 2-year-old boy who developed Henoch-Schönlein syndrome 16 days after the onset of chickenpox. Their paper illustrates the difficulty in defining Henoch-Schönlein syndrome. Chickenpox can be followed by a nonthrombocytopenic purpura: it can also be followed by a nephritis. If the two were to happen together and the child also had a tummy ache or an aching joint the diagnostic label would be Henoch-Schönlein syndrome.

As is so often the case in medicine, the more cumbersome the diagnostic label the more likely that it is being used to hide our ignorance of its pathogenesis.

Slow-release theophylline preparations

Sir,

The study by McKenzie and Baillie (*Archives*, 1978, **53**, 943) indicates the growing appreciation that theophylline has the potential to control the symptoms of chronic asthma when serum levels are maintained at between 10 and 20 μg/ml. As they suggest, sustained-release theophylline formulations offer therapeutic advantage by allowing more stable serum theophylline concentrations; this results in longer intervals between doses than are possible with either cromoglycate or β-agonist bronchodilators. Not all sustained-release theophylline preparations are completely and reliably absorbed, however, and each product differs in its absorption characteristics even when absorption is complete (Weinberger *et al.*, 1978).

The degree to which a theophylline formulation maintains acceptably stable levels relates to both the rate of absorption of the product and the rate of elimination of the individual. As children have average half-lives of elimination of 3·7 hours, slowly absorbed products are particularly important if excessive fluctuations in serum theophylline concentration are to be avoided. The clinical importance of lessening these fluctuations has been shown by the decrease in bronchodilatation (Levy and Koysooko, 1975), and blocking of exercise-induced bronchospasm that is parallel to decreasing serum concentration (Pollock *et al.*, 1977). While McKenzie and Baillie argue for the convenience of 12-hour dosing with the sustained-release preparations, their data (McKenzie and Baillie, 1978) and ours (Weinberger *et al.*, 1978) suggest that 8-hour dosing may often be more appropriate except for the slowest of the reliably and completely absorbed sustained-release preparations or for patients with slow rates of elimination.

The rate of elimination of theophylline also determines dosage (Jenne *et al.*, 1976; Ginchansky and Weinberger, 1977). The problems that can result from the variable dosage requirements for theophylline were illustrated in a study that compared theophylline with cromoglycate (Cromolyn, Intal) performed at the Hammersmith Hospital and at two residential treatment centres for asthma in Denver (Hambleton *et al.*, 1977). Whereas all of the patients in Denver tolerated theophylline, 6 patients at the Hammersmith Hospital did not, and therefore could not enter the study. The difference can be attributed to the manner in which theophylline dosage was determined. Each patient in Denver was given an individual theophylline dose while an 'average' dose, similar to that recommended by McKenzie and Baillie, was initiated in all the Hammersmith Hospital patients. The resulting intolerance in some patients was predictable (Wyatt *et al.*, 1978).

We have found that clinical titration using serum theophylline measurement as a guide gives a high degree of safety and provides the greatest likelihood of efficacy in the management of chronic asthma (Ekwo and Weinberger, 1978; Hendeles *et al.*, 1978).

Dr McKenzie comments:

We agree with Dr Weinberger that ideally the starting dosage of theophylline should be small, blood levels checked, and dosage built up. However, many of our patients live some distance from the hospital and we feel that it would be impracticable to recall these children frequently to measure levels and adjust dosage. We prefer to titrate our patients by starting with a high dosage, checking levels, and then raising or lowering the dosage as necessary. Only 2 of 65 children who started theophylline treatment with slow-release preparations in the dosage we recommended (McKenzie and Baillie, 1978) had side effects that might have been attributable to theophylline, but in neither was the blood level >20 μg/ml.

We found that the incidence of nausea and vomiting in children treated with choline theophyllinate or plain theophylline (the preparation used in the Hammersmith/Denver study (Hambleton *et al.*, 1977)) was high (McKenzie *et al.*, 1978) and that compliance, as others have found (Eney and Goldstein, 1976), was poor. These side effects may occur even when levels are within the therapeutic range or below it. We now rarely use these compounds, preferring the slow-release preparations.

We agree that serum levels may be more constant in those children with fast clearance rates if the slow-release preparation is given every 8 hours. However, it must be remembered that the efficacy of theophylline is proportional to the logarithm of the blood level (Mitenko and Ogilvie, 1973). Trough levels <10 μg/ml may give satisfactory control for many children and an extra dose just to raise the blood level would therefore be unnecessary.

Incidence of dental caries in coeliac children

Sir,

Referring to the letter on this subject (*Archives*, 1979, **54**, 166), we have submitted a paper entitled 'Gastroenteritis, coeliac disease, and enamel hypoplasia' to the *British Dental Journal*. One of the problems in such a study was the difficulty in obtaining, for histological section, teeth with enamel hypoplasia. The hypoplastic lesions are often destroyed by dental caries. We were lucky to obtain specimen teeth, in spite of the fact that we have been observing coeliac children for 20 years.

The lesions that were on the permanent incisors and on the first permanent molars were produced at the end of the first year of life. It is possible to detect the lesions before the teeth erupt by means of *x*-rays. This allows appropriate preventive or therapeutic measures to be instituted as soon as the tooth erupts.

Fucidic acid in Gunn rats. No influence on serum bilirubin concentration

Sir,

When drugs which compete with bilirubin for albumin-binding sites are injected into homozygous Gunn rats there is a decline in the level of serum bilirubin. After long-acting sulphonamides, for instance, serum bilirubin decreases to between 10 and 20% of the baseline concentration (Ballowitz and Hanefeld, 1976). The displaced, now unbound (free), bilirubin moves out of the plasma mainly into adipose tissues, including the brain, where it may lead to kernicterus. This was first described for sulphisoxazole (Gastrisin) by Johnson *et al.* (1959).

During the last decade several other drugs that are commonly used in nurseries have been subjected to appropriate tests (Brodersen, 1974; Yeary and Davis, 1974; Rayner *et al.*, 1978). Fucidic acid was not among them, as this substance is not often prescribed during the first days of life. However, we recently had to infuse this antibiotic into a newborn baby suffering from severe staphycococcal sepsis and osteomyelitis, the staphylococci being resistant to most other antibiotics.

We therefore tested IV 'fucidin soluble' ampoules (Thomae GmbH Biberach a.d. Riss, Germany) in 3- to 5-day-old homozygous, jaundiced Gunn rats. We also gave them an oral suspension 'z 141–EXT.7'+ (not yet available in Germany) containing 5 g fucidic 2·2 imidoethanol per 100 ml. The IV dose was 10–50 mg/kg, the oral dose—given by gavage—50 to 2000 mg/kg. LD_{50} of the 2 preparations, which we investigated in 3- to 5-day-old, heterozygous, nonjaundiced Gunn rats, differed markedly. It was between 50 and 100 mg/kg after IV and 1000 mg/kg after oral application. There was no effect on levels of serum bilirubin. Half an hour after IV and 3 hours after oral administration, the highest doses decreased the levels of serum bilirubin to about 80% of the baseline concentration (7·1–9·3 mg/100 ml; 121–159 μmol/l), a similar decline to that which occurs after a saline injection.

We conclude that neither fucidic acid nor the stabilisers in the intravenous preparation is a strong competitor for albumin-binding sites.

Spina bifida and maternal Rh blood type

Sir,

Spina bifida cystica (myelomeningocele) is a relatively common birth defect (one in 500 to one in 200 live births) whose aetiology is not known, although it has been suggested that a patient's children and siblings have an increased risk (Bergsma, 1973). Unfortunately, preventive measures, other than genetic counselling to affected families and prenatal screening for high α-fetoprotein levels in patients at risk, are nonexistent. We should like to report the results of a pilot retrospective study on children with spina bifida, whose parents are members of the Houston chapter of the Spina Bifida Association of America. We examined 28 cases and found that more mothers had Rh- blood type in this population compared with the general population ($\chi^2 = 6\cdot45$, confidence interval 0·02%). We found about twice as many mothers with Rh- blood type in our sample (i.e. incidence 15%) (Wiener, 1954). We are currently planning to study a much larger sample and we hope to determine the Rh-blood type of parents and all siblings, and compare the incidence of Rh-blood incompatibility, Rh haemolytic disease, early postnatal jaundice, and transfusions. We have found no reports that suggest a possible relationship between maternal Rh-blood type and spina bifida.

Book reviews

Pediatric Kidney Disease (in two volumes). Edited by Chester M. Edelmann. (Vol. 1: pp. 573; illustrated + tables. Vol. 2: pp. 769; illustrated + tables. £35.00 each volume, hardback; cased. Little Brown: Boston. 1978.

This is the 4th multiauthor textbook of paediatric nephrology in English to appear and it is the longest and most comprehensive with more than 100 contributors. It covers the whole of nephrology including physiology and renal development, pathogenesis of renal damage, clinical investigation, complications of renal disease and their management, congenital and hereditary kidney disease, glomerulonephritis, nephrotic syndrome, systemic illness and nephritis, tubular disorders and, finally, urinary tract infection and 80 pages of paediatric urology. 85% of the authors are from the USA and most are particularly associated with the Albert Einstein College of Medicine, New York, an institution which has played an important rôle in the development of paediatric nephrology and especially developmental physiology of the kidney. The editor himself has contributed considerably to these studies. The book reflects these strengths. Some of the chapters are magnificent; that by Dr Spitzer on renal physiology and functional development has 103 pages and over 1300 references providing almost a book on its own. Other chapters dealing with basic concepts, laboratory and animal research, and pathological mechanisms are equally good. The clinical sections seem by comparison to be weaker and less well organised. For instance the management of acute renal failure is dealt with in two separate chapters, beginning on pages 466 and 1108, and with renal failure and nephritis the number of authors dealing with different aspects of the problems does not make it easy to obtain practical clinical advice. No mention is made of hypovolaemia as a major complication in minimal change nephrotic syndrome, or of the value of dynamic renal scintigraphy in acute renal failure, or of congenital duplex kidneys and ectopic ureterocele, in spite of 25 pages on urologic trauma in childhood; it is not clear whether all children with urinary tract infection should have a micturating cystogram. Other minor criticisms could be made and, overall, fewer authors and some reorganisation of and within chapters would improve the book but none the less it is a major achievement. The information is not given in other textbooks on nephrology or paediatrics and the book reflects the emergence of paediatric nephrology as a specialised area of clinical and experimental work. It is well produced, reasonably (by current standards) priced, and while essentially a reference book, it is one which will be eagerly sought by doctors caring for children with kidney disease.

CYRIL CHANTLER

Surgical Management of Juvenile Chronic Polyarthritis. Edited by G. P. Arden and B. M. Ansell. (Pp. 281; illustrated + tables. £15.60 hardback.) Academic Press: London. 1978.

This 275-page monograph covers a unique experience of 30 years' treatment of juvenile chronic polyarthritis in the rheumatic unit at Taplow. With a quoted incidence of 24 per 100 000 of the population, few surgeons or physicians outside a special unit can have wide experience of the management of this condition. This book, under its 2 editors and 8 contributors, provides that information and experience, and deals not only with surgery, but also with radiology, anaesthesia, pathology, rehabilitation, and general medical problems. It emphasises the necessity for teamwork and the value of joint clinics where discussions can take place about the treatment of diseases such as this which have such widespread effects.

Surgery and anaesthesia are not without their hazards in this crippling disease, but advances in joint replacement are revolutionising what can be offered to these patients. The chapter on anaesthetic problems and the use of ketamine in patients in whom intubation is dangerous, if not impossible, is most interesting. Replacement of the hip joint is now a common and successful operation. However, the particular problems presented by these children and the special methods used to overcome them have been learnt by hard experience which is invaluable to other surgeons. Knee joint replacement remains a problem. Several types are being assessed, but none has become established in the way that the hip joint has done. Hands and feet have not been forgotten, particularly the importance of simple conservative methods, such as splints and supports.

Rehabilitation is rightly emphasised. The devastating effect in terms of joint stiffness which can result from taking a simple biopsy of the knee in the young child, is pointed out several times. The use of a prone lying couch, regular exercises, swimming, rest, and sometimes work splints, stress the importance of continuous treatment in daily life as well as in hospital. I would certainly recommend this short, readable book for anyone interested in the formidable problems presented by these children.

THE UNIVERSITY OF LEEDS

DEPARTMENT OF PAEDIATRICS AND CHILD HEALTH

DEPARTMENT OF COMMUNITY MEDICINE AND GENERAL PRACTICE

COURSE IN DEVELOPMENTAL PAEDIATRICS AND CHILD HEALTH

It is proposed to hold a further course in the academic year of 1979/80 in association with Hospital and Child Health Specialists in the Leeds Region.

The course will consist of a whole-time introductory week, commencing Monday 1 October 1979, followed by 3 ten-week terms of day-release on Wednesdays. The outline of the syllabus is as follows:

TERM I : The Child with Physical Handicaps

TERM II : The Child with Emotional and Educational Handicaps

TERM III: Current Topics in Child Health

The course is recognised under the National Health Service Regulations 1974. The whole course fee is £200.

The course will be designed so that the introductory week, the separate terms and the individual study days of the third term are each self-contained, and it will be possible to attend selected parts of the course only. The introductory week and the third term are recognised under Section 63.

Further details of the course and of fees for parts of the course, and application forms, may be obtained from Professor R. W. Smithells, Department of Paediatrics and Child Health, 27 Blundell Street, Leeds LS1 3ET, Yorkshire.

Hypothalamic and Pituitary Hormones

The Proceedings of a Symposium organised by the Association of Clinical Pathologists

Edited by G. K. McGowan and G. Walters

CONTENTS

Editors' foreword ● Anatomy of the hypothalamus and pituitary gland ● Pituitary and hypothalamic physiology ● Relationships of structure with function of the gonadotrophins ● Purification of anterior pituitary and hypothalamic hormones ● Cytochemical methods of hormone assay ● Secretion of hypothalamic and pituitary hormones by non-endocrine tumours ● Secretion of pituitary-like peptides by the human placenta ● Disorders of prolactin secretion ● Disorders of gonadotrophin secretion ● Gonadotrophin-releasing hormone ● Thyrotrophin-releasing hormone in clinical practice ● Therapeutic use of human growth hormone ● Management of acromegaly ● The posterior pituitary and diabetes insipidus

PRICE: Inland £4·00; Abroad US$10·00 including postage

Payment must be enclosed with order or a surcharge of 30p will be made for rendering invoices and statements

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751; 1978, **53**, 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged
(11) From January 1980 references in the text wil numbered. References given at the end of the pa should be listed in the order in which they are mentioned. The full title of article or book shoul given, and the first and last page numbers of the ticular paper or chapter. The titles of journals sh be abbreviated according to the style used in Ir Medicus (see *British Medical Journal*, 24 Febr 1979, **1**, 532–535).
(12) Summary to be typed on a separate sheet; it should say what was done and what was conclu

Notice to Advertisers

Applications for advertising space and rates sh be made to the Advertisement Manager, *Archive Disease in Childhood*, B.M.A. House, Tavis Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is publis monthly. The subscription rate is £28.00 in the Un Kingdom and the Republic of Ireland, and US $6 in all countries overseas. Payment for overseas scriptions should be made in US dollars, i.e. $65.50, or in your national currency based on prevailing exchange rate to the US dollar of currency, payable to the British Medical Associat Orders can also be placed locally through any lea subscription agent or bookseller. (For the conveni of readers in the USA subscription orders, wit without payment, can also be sent to: BRIT MEDICAL JOURNAL, 1172 Commonwe Avenue, Boston, Mass., 02134. All inquiries, howe must be addressed to the publisher in London.)

All inquiries regarding air mail rates and si copies already published should be addressed to publisher in London.

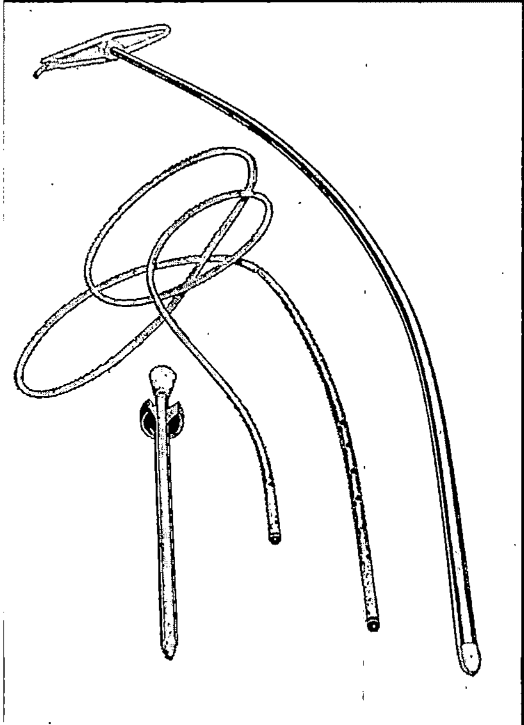
Simplicity itself



The Codman Shunt range, available only from Downs, has proved outstandingly popular with British surgeons. Here's why.

UNI-SHUNT*—the unique one piece shunt.
Simple and easy to insert, it's one piece construction reduces the risk of infection and need for revision.

ACCU-FLO*—the guaranteed system which offers complete flexibility.
The Accu-Flo range of shunts offer the surgeon a complete system from which to choose.
They are also guaranteed to function at the stated pressure. Renowned for their consistently high quality and low cost—up to 20% less than some competitive products—Accu-Flo shunts are also double sterile wrapped.
The whole range is available from stock, so there's no delay when ordering. For more details, fill in the coupon.

CHARLES C THOMAS • PUBLISHER

POISONING: Toxicology, Symptoms, Treatments (4th Ed.) *by* **Jay M. Arena.** The entire spectrum of toxic compounds is considered. Recent treatment controversies and environmental contamination receive particular emphasis. *'79, $44.50*

HOME-BASED SERVICES FOR CHILDREN AND FAMILIES: Policy, Practice, and Research *edited by* **Sheila Maybanks** *and* **Marvin Bryce.** Nineteen program descriptions outline a variety of home-based family services, with information on treatment techniques, utilization of volunteers, and funding and administrative processes. *'79, $18.00*

MEDICAL TERMINOLOGY FOR MEDICAL STUDENTS *by* **William Blake Tyrrell.** This text not only considers word history and origin, but also provides instruction for translating Latin anatomical nomenclature. *'79, cloth-$14.50, paper-$9.75*

APPLIED AUDIOLOGY FOR CHILDREN (2nd Ed., 4th Ptg.) *by* **D. M. C. Dale.** The application of audiological theory to the everyday use of hearing aids by children is clearly explained. *'79, $9.00*

GOURMET FOOD ON A WHEAT-FREE DIET (4th Ptg.) *by* **Marion N. Wood.** Concerned with the elimination of wheat, rye, barley, and oats from the diet, this book was prepared for the needs and demands of those people whose bodies cannot tolerate gluten-bearing grains. *'79, $8.75*

REFLEX TESTING METHODS FOR EVALUATING C.N.S. Development (2nd Ed., 7th Ptg.) *by* **Mary R. Fiorentino.** The text provides information on the assessment, diagnosis, and treatment of patients with abnormal reflexive reactions. *'78, $10.00*

FOOD ALLERGY AND THE ALLERGIC PATIENT: A Simple Review of Problems Encountered by the Recently Diagnosed Patient (Rev. 2nd Ptg.) *by* **E. Louis Taube.** The author outlines the fundamentals of cyclic, fixed, and masked food sensitization, classifies natural food according to food families, and discusses diet planning. *'78, $4.75, paper*

PHYSICIANS' HANDBOOK OF NUTRITIONAL SCIENCE (4th Ptg.) *by* **Roger J. Williams.** Topics include basic principles of nutritional science, internal nutrition, prenatal nutrition, biochemical individuality, and environmental effects. *'78, $11.50*

EPIDEMIOLOGY FOR THE HEALTH SCIENCES: A Primer on Epidemiologic Concepts and Their Uses (4th Ptg.) *by* **Donald F. Austin** *and* **S. Benson Werner.** This manual provides rapid understanding of epidemiologic concepts not possible with standard textbooks. *'78, $4.75, paper*

THE MALTREATED CHILD: The Maltreatment Syndrome in Children—A Medical, Legal and Social Guide (4th Ed.) *by* **Vincent J. Fontana** *and* **Douglas J. Besharov.** This text discusses the nature, causes, and extent of child maltreatment and methods of prevention and intervention. *'79, $14.50*

MATERNAL NUTRITION AND CHILD HEALTH *by* **Douglas R. Shanklin** *and* **Jay Hodin.** Evidence which establishes a direct relationship between the quality of nutrition during pregnancy and the pregnancy's success is developed. *'79, $14.75*

PRENATAL PATHOLOGY: Fetal Medicine *by* **T. V. N. Persaud.** Topics include reproductive physiology; embryogenesis; maternal-fetal relationships; pathophysiology of the conceptus; fetal disorders; and the causes, intrauterine diagnosis, and management of congenital disorders. *'79, $23.00*

PRELEUKEMIC DISORDERS *by* **Lawrence Kass.** The author discusses myeloblasts and acute myeloblastic leukemia, the similarities and dissimilarities of various preleukemic disorders, their clinical and hematologic aspects, and other related topics. *'79, $19.75*

CHILD PSYCHIATRY (4th Ed., 2nd Ptg.) *by* **Leo Kanner.** The text discusses the history of child psychiatry, basic orientation, clinical considerations, and personality problems arising from physical, psychosomatic, and behavioral problems. *'79, $19.50*

HUMAN NUTRITION: Its Physiological, Medical and Social Aspects. A Series of Eighty-two Essays (3rd Ptg.) *by* **Jean Mayer.** One of the most respected nutritionists of our time grapples with the scientific, administrative, and clinical aspects of nutrition and its relationship to health, poverty, war, and technology. *'79, $19.75*

A PICTORIAL HISTORY OF MEDICINE (5th Ptg.) *by* **Otto L. Bettmann.** This well-illustrated history of medicine covers a time span which ranges from early Egyptian culture through civilizations of the Nineteenth Century. *'79, $14.50, paper*

INTRODUCTION TO MODERN PHOTOTHERAPY *by* **Leon Goldman.** The author considers current laser light phototherapy, light art as therapy, transillumination, and the various therapeutic modalities that different portions of the electromagnetic spectrum can provide. *'78, $17.50*

MEDICAL WRITING: The Technic and the Art (4th Ed., 2nd Ptg.) *by* **Morris Fishbein.** Offering a vast amount of technical advice, this text explains the steps one should follow in preparing a paper for various audiences in various situations. *'78, $11.50*

Topics in Paediatrics 1: Haematology and Oncology

P. H. Morris Jones, *Senior Lecturer in Child Health, University of Manchester.*

Reviews the epidemiology and advances in treatment of childhood malignancy. It points out the various pitfalls and discusses the problems of intensive therapy and their management. The psychosocial diffficulties encountered by the patients and their families are dealt with in detail. New lines of treatment and some of the less common tumours are also reviewed. Finally the effects of therapy on growth and development and how the late sequelae can be handled are described.

Contents: The Epidemiology of Childhood Tumours – Cancer in Children – Presentation and Prognosis in Childhood Leukaemia – Molecular Phenotypes: A New Perspective on Diagnosis and Classification of Leukaemias – The Presentation, Management and Prognosis of Solid Tumours of Childhood – The Diagnosis and Management of Bone Tumours – The Management of Brain Tumours in Children – Hodgkin's Disease: Present Concepts and Advances in Management – Retinoblastoma – Modern Treatment – Supportive Care of Children with Cancer – Empirical Therapy in Febrile Granulocytopenic Patients – Growth and Hormonal Status of Children Treated for Malignant Disease – The Child's Response to the Stress of Serious Disease – Psychological and Social Problems in Families of Children with Leukaemia – The Parent's Reaction.

PROBLEMS OF CHILDHOOD

While in paediatrics the spotlight has, perhaps, swung recently on to behavioural and psychological aspects of child development, much of the clinician's time is still spent with acute and chronic physical disorders. Both these aspects of medical problems in childhood were reviewed in a series of *BMJ* articles published early in 1976, and these have been collected together after further revision by their authors. We hope the collection will prove useful to doctors at all stages of their careers: for children occupy a great deal of the time of every general practitioner, and confidence in their care demands both experience and knowledge.

Review article

Juvenile diabetes mellitus

Possibility of prevention

J. W. FARQUHAR

Department of Child Life and Health, University of Edinburgh

Knowledge of insulin-dependent juvenile-onset diabetes (JOD) has grown quickly during the last 5 years, particularly in three areas. (1) A small number of viruses may be associated with the development of JOD. (2) Certain genetic markers (HLA types) provide a means of identifying who is vulnerable. (3) Autoimmunity may cause more or less rapid pancreatic islet cell destruction and may be initiated in those who are vulnerable by specific virus action. The gene responsible for diabetic vulnerability may be identified in the next decade. It may then be possible to prevent JOD. Such research could be as profitable as the development of new treatment techniques.

Children form one-tenth of the recognised diabetic population in Europe and North America. The disease affects about one child in 800 under 16 years (Bloom *et al.*, 1975; Calnan and Peckham, 1977) and one young person in 300 under age 26 (Wadsworth and Jarrett, 1974). Many physicians share the impression that it is becoming more prevalent (Calnan and Peckham, 1977; Craig *et al.*, 1977).

JOD is generally insulin-dependent from the time of diagnosis or soon afterwards. The child's daily insulin injections, spaced meals, and monitoring tests may be simplified to an acceptable routine (Farquhar, 1972, 1976; Craig, 1977) but even the lightest impositions can exaggerate such behavioural flaws as already exist in him or in his family. This can cause unhappiness and tragedy (MacGregor, 1977). Mothers of diabetic children can suffer nervous strain (Olatawura, 1972) and need generous support and treatment.

For the diabetic child lies the possibility of a major disability—such as retinopathy, nephropathy, and neuropathy. Thus in the UK almost 1000 diabetics are added annually to the register of blind persons; diabetes is, at the least, the third most common cause of blindness in the age group 30–49 years (Sorsby, 1966). From the Joslin Clinic, White (1960) reported some degree of retinopathy in 93% of diabetics after 20 to 40 years. While optimal control may limit the risk (Farquhar, 1977), these statistics carry the disturbing implication that many diabetic children will have some visual handicap by the time they are between 30 and 50 years, and likely to have dependent families. The other results of microangiopathy and ischaemic heart disease are just as crippling and more life-threatening, life expectancy being about two-thirds that for normal children (Bloom *et al.*, 1975).

To the possible unhappiness and anxiety of patients and relatives must be added the cumulative economic burden to the community—hospital admissions for restabilisation, medical supplies for home control, related educational and social needs, extra care in pregnancy, and (when diabetic disability arises) long-term support for the individual and his dependants. Such massive annual cost makes attractive the direction of financial resources towards research into cure or, better still, prevention. 'Cure' may be possible when effective human pancreatic islet transplantation (*Lancet*, 1975; Turtle, 1977) or the implantation of an 'artificial pancreas' or of crossed-species islets in a micropore chamber (Gates and Lazarus, 1977) can be offered to all. The warning of Gajdusek (1979) about the possible transmission of slow virus in transplant tissue may be less relevant when fetal islets are used. Advances in prevention will cost much money but is there any hope? The evidence is now reviewed.

Clinical characteristics

JOD is characterised by three phases.

Phase 1. The acute and largely permanent process in

Department of Child Life and Health, University of Edinburgh
J. W. FARQUHAR, professor of child life and health

which hyperglycaemia, ketoacidosis, and coma develop and kill in the absence of insulin treatment. Overt infection coexists or closely precedes this phase in at least one patient in 3. Less noticeable infection may be common.

Phase 2. A phase of partial recovery commonly known as the 'honeymoon' lasting a few weeks or months when only small doses of insulin are needed or, more rarely, when it may be replaced by reducing the carbohydrate intake and adding an oral hypoglycaemic agent.

Phase 3. A subacute or chronic phase of progressive intrinsic insulin inadequacy within which diabetic control has a variable cycle of ups and downs (variable energy intake and output, variable dose of insulin, and variation in the diabetic process).

The pathological process should satisfactorily explain these phases.

Epidemiology

Physicians closely concerned with diabetes have for decades noted a tendency for new patients with JOD to cluster in time and space. They experience quiet and busy years in registering new patients, obvious variation within a year, little outbreaks within small communities, and unusual prevalence in cohort analysis of older patients. Adams (1926) recorded seasonal variations, while Gunderson (1927) was so impressed by this that he asked the question 'Is diabetes of infectious origin?'

The register of newly diabetic children (age group 0–15 years) sponsored by the British Diabetic Association gave much epidemiological information (Bloom *et al.*, 1975; Gamble and Taylor, 1976). It recorded a seasonal variation in incidence in children aged 5–15 years with peaks in the autumn and winter, although little relationship to environmental temperature was noted (Gamble, 1974). A seasonal incidence in children was also recorded by Rolles *et al.* (1975), but denied by Barbosa *et al.* (1976). Preschool children, on the other hand, showed less variation and no seasonal pattern. Age incidence in the register seems to be bimodal with peaks at about 5 and 11 years when children are joining primary and secondary schools. There is no consistent relationship to growth or puberty. During the years 1973–74 the incidence varied from 4·78 to 10·61 per 100 000 children each year geographically. In spite of a financial incentive to notify new cases to the national register, it seems that staff in some parts of the country (for example London) were less likely to do so than in other parts. Thus the register probably underestimated the number of children with JOD.

Lastly there were some surprising outbreaks within families—diabetes developing almost simultaneously in 5 cases in two years. In one family there were 3 siblings. Does JOD result from infection? If so how often, and is it preventable?

An environmental factor

The possibility of an infective cause was raised by Harris (1899) when he described the rapid development of diabetes after mumps. The same association was described by others—such as Cole (1934), Melin and Ursing (1958), Hinden (1962), and McCrae (1963). Since then there have been many reports on animals and man. Indeed Brown (1956) stated 'the most common cause of diabetes in children is a systemic infection which injures the islets of Langerhans'.

Animal diabetes. The virus of foot-and-mouth disease was linked with the development of diabetes mellitus in some cattle by Barboni and Manocchio (1962). In 1965 Craighead reported an association between encephalomyocarditis (EMC) virus and pancreatitis in mice. Subsequently he showed that EMC virus multiples in the pancreatic β-cells of mice to produce diabetes mellitus and pancreatic islet histology which closely resembled that in JOD (Craighead, 1975, 1976, 1978). He showed that the islet insulin increased 3-fold before falling to very low values. These and further studies by Ross *et al.* (1975) and Boucher *et al.* (1975) established that diabetes mellitus was produced only when a particular breed of mouse was used and only when the infection was caused by the M variant of EMC virus. Five very similar strains failed to invade the pancreatic β-cells. This work was reviewed by Notkins (1977) and indicated the need for a genetic factor both in the host and in the infecting agent. Another interesting observation was the failure, even of M strain EMC virus, to induce diabetes in athymic (nude) mice although it did so in suitable controls (Buschard *et al.*, 1976).

Similarly, Coleman *et al.* (1973, 1974), Gamble (1975), and Smith and Deibel (1975) showed that a specified breed of mouse could be made diabetic by infecting it with Coxsackie virus B4, the pancreatic islet histology again resembling the findings in JOD. This is particularly interesting in view of observations in man.

Child diabetes. The association with mumps seems clear but it may contribute very little to the annual incidence of JOD. Notkins (1977) stated the obvious—that mumps is common but complicating diabetes is rare. It should be remembered however that months (Melin and Ursing, 1958), or years

(Sultz *et al.*, 1975), may separate the infection from the recognition of diabetes. The report of a patient with JOD after inoculation with a live-attenuated mumps vaccine (Sinaniotis *et al.*, 1975) will be discussed later.

Rubella virus

The development of diabetes was described in a patient after congenital rubella (Menser *et al.*, 1967) and was followed by a series of well substantiated reports on other patients (Menser *et al.*, 1978), many of whom had insulin-dependent JOD. Experimental work with rubella virus on pregnant rabbits produced histological changes in the fetal pancreatic β-cells similar to those produced in mice by EMC virus.

Coxsackie B virus

British research focused attention on the possible role of Coxsackie B virus. This began (Gamble *et al.*, 1973) with the observation that Coxsackie B4 (CB4) virus was more often found in new patients with JOD aged 10 to 19 years than in control subjects, although the significance of this may now be uncertain. A matching seasonal incidence was also noted. This hypothesis is being developed and applied to HLA typing (Cudworth *et al.*, 1977).

Acute JOD has been described in a boy of 18 months who had a high titre of CB2 and of CB-specific IgM (Wilson *et al.*, 1977). Three unrelated young adults developed acute diabetes in association with symptoms suggesting a virus illness (Gibbs, 1974). All 3 had ECG changes suggesting a myocarditis which was assumed viral.

Nine of a cluster (in time and space) of 12 patients with JOD were investigated by Huff *et al.* (1974); 8 of the 9 had suffered a recent 'viral illness', mainly respiratory. No single virus test in a panel of 26 common viral agents was positive in all, but CB3 was proved in 33%, compared with 6% of the controls.

In one family reported by Nelson *et al.* (1977) in which both parents were diabetic, 3 of their 5 children developed classical JOD within 4 months. One had an attack of Bornholm disease one month before developing diabetes and was found to have high antibody titres to CB1 and CB5. Another had a low antibody titre to CB2.

Baum *et al.* (1974) tested 11 new patients with JOD for evidence of recent infection by a wider range of viruses including CB1–5, but none was found.

A population was studied in the Pribilof Islands (Behring Sea) 5 years after an epidemic of CB4 infection. Those with serological evidence of previous infection were given glucose tolerance tests, but there was no evidence of increased prevalence (Dippe *et al.*, 1975). Subsequent appreciation of the susceptibility to diabetes of persons sharing the same HLA type (described later), and the possible protection of others, robbed the Pribilof study of some of its value. The indigenous Alaskan in these islands is not Caucasian and might not have been vulnerable to CB4 infection (Cudworth *et al.*, 1975). This point was agreed by Dippe *et al.* (1975).

So the case remains unproved but may be partly true. Kono (1976) stated that CB3 and CB4 can be isolated from the human infant's pancreas. Further work on this association is justified in the light of the reports on fetal rubella (Menser *et al.*, 1978).

Other infections

A major epidemic of infective hepatitis in West Africa was reported to have caused diabetes mellitus (Adi, 1974; Osuntokun, 1974) and, in Australia, a young man became acutely diabetic during an attack of infectious mononucleosis (Burgess *et al.*, 1974).

An inherited factor

Diabetes in relatives. The experiments already described with viruses and mice established that, for the mouse model, the genetic complement of the host is essential to the production of diabetes mellitus. This will now be examined by looking closely at diabetes mellitus occurring in relatives.

Children of diabetic mothers

Long-term follow-up studies on large populations of such children are difficult but information (Farquhar, 1969) strongly suggests that the incidence of diabetes should be high. White (1959) reported that 9% of such offspring were diabetic by age 14 and that a further 14% had chemical diabetes (see below). It is important to remember that most of the mothers in the Edinburgh study (Farquhar, 1969) had type 1 diabetes—that is, they were insulin-dependent young diabetics.

Children of conjugal diabetics

One study of such children (Cooke *et al.*, 1966) gave an incidence of 4·4%, and there were earlier studies by West (1960), Post (1962), and Simpson (1964). In the light of later knowledge it is interesting to find that diabetes was found more often among children whose parents had become diabetic early in life. The facts that earlier workers did not discriminate between JOD and MOD (maturity-onset diabetes), and that chemical testing for diabetes was too often more a matter of opinion than of science, lead to difficulties of interpretation. Thus the study by Rojas *et al.* (1969) noted the ages of the young people but not of the parents at the time of their becoming diabetic. The parents cannot therefore be assigned to the JOD or MOD group. It was concluded that the only revealing test was a poor initial insulin response to glucose in those whom it had been decided were 'prediabetic', postulated as a defective glucose-responsive mechanism for insulin secretion. In another paper Kahn *et al.* (1969) estimated from such tests that 40% of those born to conjugal diabetics had evidence of chemical diabetes.

Radder and Terpstra (1975) studied the children of patients with conjugal MOD, mean age at diagnosis 61 years. About 45% of these children were chemically diabetic on oral glucose tolerance tests but fewer than one child in 4 had previously been diagnosed. The diagnosis related to the offspring being overweight. Similarly in the study by Tattersall and Fajans (1975a) most of the parents had MOD, with a mean age at diagnosis of 54·5 years. The 'children' had a mean age of 32·6 years and 28% had impaired glucose tolerance, 2% had JOD. It was estimated that 60% would give positive results to tests by age 60 years and it was rightly concluded that results based on the offspring of 2 patients with MOD cannot be assumed to be relevant to children of 2 patients with JOD.

Siblings of diabetics

Investigators in the 1950s and 1960s half-expected to find 'heterozygotes' with abnormal glucose tolerance (chemical diabetes) among the siblings of patients with JOD. Indeed, Fajans and Conn (1954) found 19% of young adults with diabetic glucose tolerance tests. When such siblings develop insulin-dependent diabetes the diagnosis is not in doubt, but when they do not, their subjection to batteries of tests and the correlation of results widen the range of possible interpretation (Kahn *et al.*, 1969).

Thus 16% of siblings were classified as being chemically diabetic by Jackson *et al.* (1968) and 11% were so classified by Rosenbloom *et al.* (1972). Rosenbloom (1975) subsequently investigated glucose tolerance in a large group serially and found that 0·5% had overt JOD and that fewer than 5% had chemical diabetes by his standards. Adult siblings were studied by Kobberling *et al.* (1969) who estimated that 39% had chemical diabetes. It now seems less likely that their diabetes was that of the propositi.

Identical twins

A selected series of identical twins was studied and reported (Pyke and Taylor, 1967; Pyke *et al.*, 1970; Nelson *et al.*, 1975). More than half the pairs have proved to be discordant for diabetes but Rosenthal *et al.* (1976) argued that there would be concordance in at least 80% if the series were followed up. Certainly concordance for MOD is almost 100% in identical twins after age 40 (Gottlieb and Root, 1968; Tattersall and Pyke, 1972). The latter study is nevertheless interesting in that the older the discordant twins become the more likely they are to develop insulin-dependent JOD. The results of extensive virus studies are given by Nelson *et al.* (1975). While it is disappointing that there was little difference in antibody levels between the diabetic and unaffected twins, it was acknowledged that only a few were examined within 2 years of diagnosing diabetes. It was suggested that the non-diabetic twins may have had too low a dose to cause pancreatic damage.

Triplets, claimed to be monozygotic, discordant for diabetes were described by Ganda *et al.* (1977). The first developed JOD at age 13 years. The second had normal glucose tolerance tests until she became diabetic at age 21. The third remains normal on testing.

Parents and ancestors

The clearer separation of diabetes mellitus into two main groups—type 1 or JOD, and type 2 or MOD—has made family studies more meaningful. Thus MacDonald (1974) compared the ancestors of patients with type 1 with a control group and found an equal incidence of diabetes mellitus, surprising as this may be for several reasons. Separate groups of JOD and MOD (of the young) were studied by Tattersall and Fajans (1975b). Only 11% of those with JOD had a diabetic parent compared with 85% of those with MOD. In only 6% of those with JOD had the disease been present in three generations compared with 46% of those with MOD. These studies give further evidence of genetic heterogeneity in diabetes mellitus.

Disease associations

Insulin-dependent JOD can be associated with disorders ranging remarkably from Down's syndrome (and other chromosomal abnormalities) to coeliac disease, and from autoimmune endocrinopathies to nerve deafness and optic atrophy. The nature of the diabetes may differ in the disorders listed in the Table but there is doubtless a message in these associations for him who finds the cypher.

HLA antigens

family possessing diabetic relatives, picks out this r that child's pancreatic β-cells for destruction. As n the selectively bred mice, an unknown number perhaps all) of these individuals are genetically ulnerable. Those at greater than normal risk can ow be identified by HLA tissue-typing because hey possess in greater than normal degree a number f identifiable antigens. Minor differences, caused erhaps by inherent instability, in relevant alleles nay even explain the surprising discordancy for liabetes between monozygous 'identical' twins.

The antigens associated with JOD are B_8, BW_{15}, $_{18}$, BW_{35}, A_1, AW_{30}, DW_3, DW_4, CW_3, DRW_3, nd DRW_4. Reports on individual antigens are riefly reviewed. Changes in nomenclature are ommon and can be confusing.

ndividual associations. Cudworth and Woodrow 1974) and Nerup *et al.* (1974) noted that B_8 was nore common in patients with JOD—54% compared with 31·8% in controls. Others found it to be ven more common. The relative risk for developing JOD was given as 2·12 but was later increased in hose under 30 years to 2·5 (Cudworth and Woodrow, 1976; Nerup *et al.*, 1976). It was found to be increased also in congenital rubella (Menser t al., 1974). The significantly higher representation of B_8 in differing degree in JOD has been reported in many papers from different communities (Löw *et al.*, 1975; Rolles *et al.*, 1975; Barbosa *et al.*, 1976; Landgraf *et al.*, 1976; Morris *et al.*, 1976; Pointel *et al.*, 1976; Savi *et al.*, 1976; Vialettes *et al.*, 1976; Barta and Simon, 1977; Illeni *et al.*, 1977; Koivisto *et al.*, 1977; Ludwig *et al.*, 1977). Illeni *et al.* (1977) found the increase in B_8 to be significant in the 0–5-year age group. This antigen was found not to be increased beyond the expected normal in Sardinia despite a high prevalence of diabetes (Contu *et al.*, 1976). It should be noted that HLA-B_8 is uncommon in the Aleutian people of the Pribilof Islands (Menser *et al.*, 1974).

Cudworth and Woodrow (1974, 1975a,b, 1976) reported increased representation of BW_{15} and a relative risk of 1·85. Similar experience was recorded by Nerup *et al.* (1974, 1976), Löw *et al.* (1975), Morris *et al.* (1976), and Solow *et al.* (1977), but not in rubella by Menser *et al.* (1974, 1978). In Sardinia, Contu *et al.* (1976) found it in 11·4% of patients with JOD but in only 2% of the rest. It was not increased however in studies made in France (Pointel *et al.*, 1976) or Finland (Koivisto *et al.*, 1977).

The coexistent increased representation of B_8 and BW_{15} may have a significant effect. Nerup *et al.* (1976) suggested an increased risk to siblings of the propositus, while Koivisto *et al.* (1977) found it at its greatest when JOD coexisted with coeliac disease. Barta and Simon (1977) found increased representation of B_8, but not of BW_{15}, in Hungary. When they looked at coexisting B_8 and BW_{15}, however, it was present in 15–16% of patients with JOD but in only 0·9% of controls. From this they calculated relative risks for B_8, and for B_8 and BW_{15} at 2·027 and 18·25 respectively. Cudworth *et al.* (1977) however estimated the relative risk of B_8 and BW_{15} at 5·59.

Cudworth and Woodrow (1976) reported increased representation of B_{18} in patients with JOD and calculated the relative risk to be 2·56. According to Vialettes *et al.* (1976) B_{18} occurs in 26·6% of those with JOD compared with 11·8% in the general population.

Contu *et al.* (1976) reported that BW_{35} was present in 29·2% of patients with JOD compared with 12·5% of the nondiabetic population. In Italy Savi *et al.* (1976) found it was present in 38% of those with JOD compared with 23% in controls in Parma, while Illeni *et al.* (1977) reported from Milan that BW_{35} was significantly decreased in those with JOD.

Morris *et al.* (1976) found A_1 to be over-represented in insulin-dependent diabetics, the proportion being greater in those with thyrogastric antibodies and persistence of pancreatic islet cell antibodies for more than 5 years (see later). Vialettes *et al.* (1976) found the antigen was almost twice as common in diabetics described as 'low-insulin responders' to glucose, likelier perhaps to be MOD or MODID (maturity-onset diabetes insulin-dependent).

AW_{30} antigen is increased (Illeni *et al.*, 1977) in JOD patients diagnosed between October and January and this could be related to a specific seasonal infection.

DW_3 and DW_4 are associated even more strongly than B_8 and BW_{15} with JOD (Nerup *et al.* 1976). DW_3 and DW_4 were found in 80% compared with 24% in controls, as stated also by Hsu *et al.* (1977); its importance was also noted by Bottazzo and Doniach (1976) and Irvine *et al.* (1977a).

The increased representation of CW_3 in JOD is described by Ludwig *et al.* (1977).

DRW_3 and DRW_4, the alloantigens found on B-lymphocytes, are believed to carry a relative risk of 4·5 and 2·5 respectively (Schernthaner *et al.*, 1977).

The importance of B_7 (Ludwig *et al.*, 1977) lies in its significantly *low* representation in JOD (13·2% v. 26·8% in the normal population).

The technique of HLA-typing now makes possible the recognition of an individual who is likely to develop JOD when appropriately challenged. The exact locus and nature of the fault is likely to be found as HLA mapping continues.

Viral association. Of HLA-B_8-positive patients with JOD reported by Rolles *et al.* (1975) 81% presented between October and the end of February, whereas those with HLA-B_8-negative JOD presented throughout the year. The late autumn and winter period coincides with the highest incidence of Coxsackie B virus infections. This was not the experience of Barbosa (1977). Cudworth *et al.* (1977) recorded twice as many new patients with JOD in autumn/winter as in spring/summer. They reported BW_{15} clustering in winter but not in the previous autumn. They also reported that new patients with JOD with BW_{15}, and especially with B_8 and BW_{15}, had higher neutralising antibody titres to Coxsackie B virus strains 1–4.

β-Cell destruction and autoimmunity

Histology. Death is rare in diabetic children and adolescents who attend good clinics. Pathologists therefore have little chance to examine the pancreas from recently diagnosed young diabetics. Gepts (1965, 1976) has attracted material from other centres and has acquired great experience. He described a characteristic lymphocytic insulitis in the pancreas of young people dying within 6 months of diagnosis. This looked like a response to direct viral aggression or an immune reaction and it is seldom seen in patients who die after being diabetic for one year. It may well indicate the process by which β-cell function is more or less suddenly interrupted, recovers briefly, and is then lost steadily. Similar histology was described in a child who died from congenital rubella (Bunnell and Monif, 1972), and the virus may persist in human pancreas for months or years (Cooper *et al.*, 1965). Gepts *et al.* (1977), using new immunocytochemical methods, found that β-cells could be identified in JOD of recent onset. In chronic JOD the atrophic islets are composed mainly of glucagon, and of somatostatin cells. In addition the JOD pancreas contains ribbon-like cells considered to secrete pancreatic polypeptide. Hyperplasia of such 'HPP cells' in JOD is thought to represent atypical islet regeneration induced by severe and prolonged injury to pancreatic endocrine tissue.

β-Cell changes, similar to those found in mice made diabetic by EMC virus, were consistently found in the offspring of rabbits infected with rubella during pregnancy (Menser *et al.*, 1978).

Association with autoimmune diseases. A clinical association between diabetes mellitus and diseases characterised by organ-specific autoimmunity is well recognised and documented (Carpenter *et al.*, 1964; Irvine *et al.*, 1967) and its familial character has been reported by Bottazzo *et al.* (1978). Antibody evidence of thyroid and gastric autoimmunity was given by Irvine *et al.* (1970) who concluded that there seemed to be 'a disorder of the immunological system related to insulin-dependent diabetes'. The subject was reviewed by MacCuish and Irvine (1975).

Pancreatic islet-cell antibodies (PICA). These were reported by Bottazzo *et al.* (1974) and have attracted much attention and caused some controversy, but their existence is not in doubt. Debate continues on whether they result from pancreatic islet cell damage or represent the attacking process. They are certainly associated more with insulin-dependent JOD than with MOD, although the latter may be divisible into those with and those without PICA. Those patients with MOD and PICA may be controlled by oral hypoglycaemic agents, and Irvine *et al.* (1977a, b) suggested that they represented a less severe form of JOD in those who will eventually require insulin. PICA are classified as IgG (MacCuish *et al.*, 1974a; Lendrum *et al.*, 1975). According to Lendrum *et al.* (1976) they are found in fewer than 2% of non-diabetics, in 5% of insulin-independent diabetics, and in 38% of those who are insulin-dependent. They are detectable however in 85% of JOD immediately after diagnosis and decrease with time. Irvine (1977) suggested that in some there is such sudden islet cell death that PICA are not found at any stage. If they represent only the response to attack, then their usefulness in prevention or restriction of damage is limited; but Irvine *et al.* (1976) gave some evidence of their presence in nondiabetic patients with other autoimmune problems.

Tests of immune response. Cellular sensitivity to an extract of human pancreas assessed by MacCuish *et al.* (1974b), using the leucocyte migration test, gave abnormal results only in young JOD. Patients with JOD and controls were tested by Richens *et al.* (1976) for cellular sensitivity to pancreatic preparation, liver mitochondrial, and CB4 virus. The JOD response was again increased to pancreas and to mitochondriae but it did not differ from controls when tested with CB4. There was a suggestion of CB4 hypersensitivity 3 months after diagnosis.

Huang and Maclaren (1976) demonstrated significant cytoadherence and cytotoxicity to human insulinoma cells *in vitro* when compared with controls. They favoured the hypothesis that JOD is a 'disease of autoaggression' and that lymphocytes and not antibodies deliver the attack on pancreatic β-cells. The role of T-cell suppressor function was studied by Horowitz *et al.* (1977). It was successfully demonstrated in all controls but was deficient in 6 of 9 patients with JOD.

The destructive device. What changes an apparently healthy child into one with JOD within days or weeks? Rubella and mumps certainly seem to trigger a genetic time-bomb with a delayed action system. While it is impossible to disregard the negative virus study from Oxford (Baum *et al.*, 1974), it only excluded appropriate antibody responses to that panel of viruses about which evidence was sought. Recent history confirms that previously unrecognised micro-organisms are responsible for serious diseases of which the aetiology was unknown (Gajdusek, 1979). Reports strongly suggest the involvement of Coxsackie B viruses and there may be others. Alternatively a failure to raise antibody may be a meaningful observation, but this would then be out of step with the fact that CB4 antibody was more common in patients with JOD than in controls (Gamble *et al.*, 1973). Perhaps a time factor, as in rubella, or fatigue or stress, as in paralytic poliomyelitis, also operate. Certainly a small but varied group of infective triggers to the device would explain the epidemiological facts.

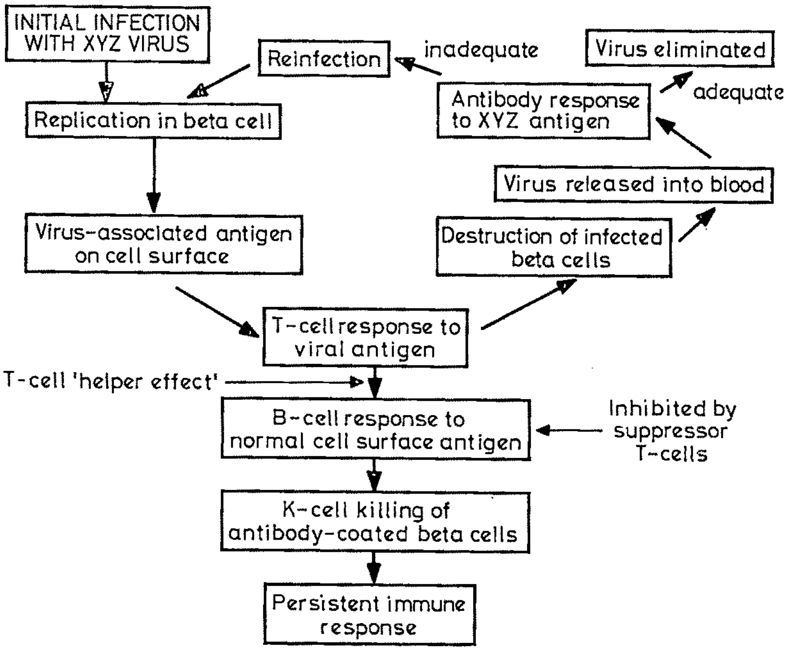
Only a small minority of the population carries the next stage of the destructive device. Alternatively it is made safe by age. Thus either all potential patients with JOD are triggered in their early years or some escape the initial attack (virus) when the device is sensitive. Age certainly has some influence as it would seem, for example, that rubella is only insulopathic when prenatally acquired although this has still to be proved. Few people escape rubella and mumps in their first 20 years and scarcely any become quickly diabetic in association with it.

The usefulness of HLA-typing in the identification of those who are vulnerable is apparent, but why do these particular types carry an increased risk of β-cell destruction? Intra-HLA recombination has been shown by Suciu-Foca and Rubinstein (1976) to be less than 1% in offspring of apparently normal parents (6 crossovers in 2000 babies in 600 families). They claim it to be 15% however in families containing one or more person with JOD. They suggest the existence of a gene which increases the rate of recombination (that is chromosomal instability) in at least a segment of human chromosome 6. In cases where the individual is homozygous it may be associated with the appearance of JOD. Others share this view that the specific antigens already reviewed closely adjoin an immunoreactive gene concerned somehow with the autoaggressive reaction. The β-cell receptor may favour the attachment of specific viruses. A series of possible effects follow, analagous perhaps to those in response to hepatitis B virus* (HBV) shown in the Figure, taken from Eddleston and Williams (1974). A direct attack may cause β-cell death. Alternatively the process of virus replication in β-cells is sublethal to them and the damage is mediated by a host immune response. Virus-associated antigen on the cell surface provokes a T-cell response with destruction of infected β-cells, release of virus, antibody response, and either the end of the attack (if all virus is eliminated), or reinfection of surviving β-cells. T-cell 'helper-effect' may stimulate β-cells to produce antibody which attaches to virus antigen or virus-associated antigen on the cell surface.

K-cells would then kill the antibody-coated β-cells. This reaction should be time-limited by suppressor T-cells and failure would lead to a sustained attack. Lastly there is the possibility of a delayed immune response in which T-cells, alerted to seek and kill minor deviations from normality, sustain an autoaggressive action on surviving β-cells

---

*Anti-Hbs and hepatitis were in fact found more commonly in diabetics than in nondiabetics by Hasslacher *et al.* (1973) but, while more frequently seen in patients with JODs rather than those with MOD in a later study (Hasslacher *et al.*, 1977), the prevalence had fallen to that in the nondiabetics. Previous patient-to-patient transmission and subsequent improvement in disposable syringes, needles, etc. are thought to explain the change.



INITIAL INFECTION WITH XYZ VIRUS
Reinfection
inadequate
Virus eliminated
adequate
Antibody response to XYZ antigen
Replication in beta cell
Virus released into blood
Virus-associated antigen on cell surface
Destruction of infected beta cells
T-cell response to viral antigen
T-cell 'helper effect'
B-cell response to normal cell surface antigen
Inhibited by suppressor T-cells
K-cell killing of antibody-coated beta cells
Persistent immune response

Figure *Hypothesis for pancreatic β-cell damage and JOD.*

so that the child's own virus-modified cells maintain the process. Such a hypothesis could explain the clinical variations in JOD. Overwhelming infection could produce those cases in which symptoms of diabetes are virtually simultaneous with those of acute infection. Indeed, certain virus infections may be associated with pancreatic β-cells more often than is realised. The rare case of apparent complete recovery may represent the rare defensive success; or perhaps it is common and diabetes fails to develop.

Case report

In 1972 I admitted a 4·7-year-old girl who had suffered for a day or two from diarrhoea and vomiting. She was found to have diabetic ketoacidosis. Within hours of her admission her 20-month-old sister was admitted with identical symptoms but without diabetes. The elder child responded well to insulin and intravenous fluid. She was discharged within a week and has remained completely well for over 5 years. Her oral glucose tolerance test in 1978 and July 1979, when the blood glucose 2 hours after a glucose load was 5·2 mmol/l (93·7 mg/100 ml), was absolutely normal. The younger sister was also discharged within a week and remains well. From neither case was a virus recovered on culture. In July 1979 her blood glucose 2 hours after a glucose load was 4·6 mmol/l (82·9 mg/100 ml). The initial blood specimen from the elder child was unfortunately inadequate for a Coxsackie B neutralising antibody test. The second specimen however had a titre of 1024 for CB2. The younger (nondiabetic) child had a CB2 titre of 64 in the first and second specimens. In both sisters the titres for B_1, $_3$, $_4$, $_5$, and $_6$ were less than 16 .There was local scepticism about the significance of these results in 1972 and no further samples were taken. The stability of the younger sister's titre in 1972 may suggest a previous infection, rather than a response to the infection which led to the admission. The elder sister's titre exceeded the younger's by a factor of 16. Does this imply that the infection was more severe or that the response was exaggerated? And why, if the infection was an old one, did the diabetes develop severely at the time it did and as a brief phenomenon?

Between these two extremes may lie a range of diabetic progress reflecting the autoimmune response, the acute episode, the 'honeymoon', β-cell atrophy, the development of ribbon-like cells, secretion of polypeptide, and the downward drift of insulin secretion, with oscillations, especially during re-encounters with the virus, until a steady diabetic state is achieved. The contention (Irvine *et al.*, 1977a) that some young diabetics controlled on oral hypoglycaemic agents for varying periods until insulin injections are obligatory are JOD in the making (MODY) rather than MOD is consistent with this. PICA in blood would then be expected for a much longer period.

The observation by Block *et al.* (1973) that C-peptide may be detected for several years after diagnosing JOD signifies continuing but failing insulin secretion. It has been repeated recently by Werther *et al.* (1978).

Speculation

It is now possible to screen by HLA-typing the offspring and the siblings of patients with JOD for vulnerability. It is costly as an individual test but, if there were a means of protection, such an initial outlay would be miniscule compared with the cost and the suffering involved in a life-time of diabetic care. Rubella vaccine should eliminate the presumably small problem of future JOD being produced by prenatal rubella infection. Mumps vaccine is available but more information is needed about JOD arising after vaccination. Such protection however is unlikely to contribute much to a programme designed to eliminate JOD.

A polyvalent CB virus vaccine is presumably possible and could prevent much morbidity other than diabetes. As with mumps vaccines, clinical trials on people likely to be vulnerable would need to be conducted with care. Once pronounced safe, it might be better to immunise all offspring and all siblings of patients with JOD, rather than to categorise them by HLA-type for vulnerability. In either, the obstetric history of birthweight for gestational age and for fetal malformations would be of great interest. A study of vaccinated and unvaccinated siblings might help to establish the aetiological role of CB virus strains.

Whether the use of highly-purified porcine insulins for maternal control or fastidious blood glucose control during diabetic pregnancy will prevent pancreatic islet fibrosis in the fetus and future JOD is still a matter for speculation, and a source of fetal lymphocytes for HLA-testing in early pregnancy remains unavailable. It is desirable however that such pathological material be pooled and expertly examined, as provided by the diabetic pregnancy study group in Europe. Perhaps the attachment of iatrogenic maternal insulin antibody or the overstimulation of fetal β-cells causes structural change capable of initiating an autoaggressive response. The answer may come when the gene defect, to which investigators now seem so close, is identified. The absent or abnormal response may prove correctable or the vulnerable child may be protected from its attack. Cahill (1976) optimistically says, 'New cases of juvenile diabetes may be prevented if our present rate of knowledge about the disease continues to grow over the next 2 or 3 years at the rate that it has for the past 5 years'.

Status asthmaticus in children

A one-year study

SHEILA A. McKENZIE, A. T. EDMUNDS, AND S. GODFREY

Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital

SUMMARY 50 children were admitted on 72 occasions during one year in status asthmaticus, defined as wheezing not relieved by two doses of bronchodilator 4 hours apart. At least one-third of children were hypercapnoeic on admission. They were managed with either oral prednisolone and nebulised salbutamol or IV aminophylline and hydrocortisone in addition to salbutamol. Those with peak expiratory flow rates of >25% expected for height were satisfactorily managed on the oral regimen. One child needed assisted ventilation. 73% were fit for discharge within 4 days and more than half of them needed a change in maintenance treatment.

About 40 children between ages one and 14 years die each year in England and Wales from acute asthma. This represents about 10% of all deaths due to diseases of the respiratory system in the same age group and is equal to about 8% of all deaths due to motor accidents (Office of Population Censuses and Surveys, 1977). In the mid-'sixties the death rate from asthma was even higher, particularly in the 10–14 age group (Speizer *et al.*, 1968a). In the subsequent analysis of events leading up to asthma deaths in young people (Speizer *et al.*, 1968b; Fraser *et al.*, 1971; Inman and Adelstein, 1969) 80% of such deaths were considered to have been 'sudden and unexpected'. In 39% the severity of the terminal attack had not been appreciated by doctors or relatives, and many children had not received corticosteroids during the attack. In a study of deaths from asthma outside hospital between 1963 and 1974 (Macdonald *et al.*, 1976) the associated factors were similar. In addition, several patients had died within a week of discharge from hospital after being treated for severe asthma, and it was suggested that physiological and blood-gas abnormalities had not resolved before their discharge.

In an examination of possible reasons for the recent increase in hospital admission rate for acute asthma in children (Department of Health and Social Security, and Office of Population Censuses and Surveys), Anderson (1978) suggested that there might have been not only a change in morbidity but also a change in criteria for admission.

The purpose of the present study was to examine the factors leading up to the admission of children in status asthmaticus, to determine the severity of the attack, and to try to provide guidelines for management and admission policy.

Patients

During the period from 1 September 1976 to 31 August 1977, 50 children (29 boys and 21 girls) were admitted to this hospital on 72 occasions in status asthmaticus. This was defined as an acute wheezy episode not responding to two doses of bronchodilator 4 hours apart, given either at home or after arrival at hospital. 37 were admitted once, 9 on two occasions, 3 on three occasions, and 1 on eight occasions. This last child will be discussed separately. Therefore, 64 admissions will be considered.

As there is a specialist asthma clinic at the hospital to which children are referred from outside the district, the population from which the admissions were drawn may not have been representative of that served by the average district hospital. Table 1 gives the ages and treatment categories and locality of the children, both those attending the clinic and those admitted to hospital during the period of the study. The children in outpatients were managed as described by Godfrey (1977). For the clinic group, if a child had changed his treatment during the year he

Not local	26	32†

*10 of these children did not attend the clinic. †3 of these children did not attend any hospital clinic and 5 were known severe asthmatics attending clinics outside the area.

was classified according to the treatment he was receiving at the end of the study. For the admission group, if a child was admitted more than once he was classified according to the treatment he was receiving before his first admission. Parents were advised to seek the help of their general practitioner, bring the child to casualty, or telephone the hospital if the child's wheezing did not respond to his usual bronchodilator.

Methods

Assessment of severity and investigations. At the time of admission, the house officer recorded details of events leading to admission, including possible precipitating factors, number of previous hospital admissions, and current maintenance treatment. The length of the attack was taken from the time the child started to cough or wheeze until the time of admission. Details of physical examination including measurement of pulsus paradoxicus and investigations performed at the time of admission were also recorded. Each child was given a score for respiratory distress—the clinical score (Table 2). This is a modification of the pulmonary index score of Dabbous *et al.* (1966). The investigations, performed on admission whenever possible, were blood–gas analysis, peak expiratory flow rate (PEFR) measurement, and chest *x*-ray; nasopharyngeal swabs for viral culture and serum for respiratory viral titres were also collected. A specimen of convalescent serum was collected if possible 10–20 days later. Blood was taken for theophylline measurement if the child had received any theophylline compound.

Table 2 *Clinical score*

	Score			
	0	*1*	*2*	*3*
Wheeze	0	Expiratory	Inspiratory and expiratory	Audible without stethoscope or absent
Hyperinflation	0	+	++	+++
Use of accessory muscles	0	+	++	+++

Initial treatment. The patients were assigned one of two treatment regimens according to the severity of illness on admission. Children who met one criterion listed in Table 3 were given the intravenous regimen; otherwise they received the oral one.

Oral regimen

This consisted of prednisolone 2 mg/kg per day in two divided doses and salbutamol inhalations 2·5 mg of respirator solution in 3 ml saline every 4 hours. Salbutamol was given via a Wright's nebuliser with a flow of oxygen of 8 l/min from a wall supply. Those children who were already taking theophylline preparations continued to take them. If the symptoms or PEFR had not improved in 1–2 hours after admission, treatment with the intravenous regimen was started.

Intravenous regimen

The fluids and the intravenous drug dosages are given in Table 3.

All children received IV boluses and infusions of hydrocortisone and aminophylline. Salbutamol was given either intravenously or via a Wright's nebuliser every 4 hours. The order in which each child received

Table 3 *Intravenous regimen*

Criteria for treatment	Dehydration PaO_2 <8 kPa $PaCO_2$ >5 kPa PEFR unrecordable on Wright's peak flow meter
Fluids	Dextrose 4%, saline 0·18%, 70–120 ml/kg per 24 hours
Drug boluses	Hydrocortisone 2 mg/kg +Aminophylline 6* mg/kg over 5 minutes + either salbutamol 5 × 10^{-3} mg/kg over 5 minutes or nebulised salbutamol 2·5 mg respirator solution in 3 ml saline
Drug infusions	Hydrocortisone 1 mg/kg per hour + Aminophylline 1 mg/kg per hour + either salbutamol 5 × 10^{-3} mg/kg per hour or nebulised salbutamol 2·5 mg respirator solution in 3 ml every 4 hours

*At first aminophylline was given as a bolus of 4 mg/kg and an infusion of 0·7 mg/kg per hour. The dose was increased as serum theophylline concentration after 2 hours' treatment was consistently below the optimum therapeutic range (10–20 µg/ml).

the drugs and the route of administration of salbutamol was random as another trial was in progress to compare the effects of these drugs. This did not affect the results discussed in this paper and will be reported separately. The dose of aminophylline was modified in those children who had recently received a theophylline preparation (McKenzie *et al.*, 1978). Serum theophylline was measured 2 hours after the infusion was started and the rate of infusion was altered if this did not come between 10 and 20 μg/ml.

Antibiotics were given if the child had a fever and signs consistent with infection in the chest *x*-ray taken on admission. Oxygen was given by face mask to any child who was hypoxic and blood-gas analysis was repeated if there was no clinical improvement or improvement in PEFR after 4 hours of treatment.

Recovery phase. Once dehydration had been corrected and the PEFR had shown a sustained improvement to 30% of expected for height, IV treatment was replaced by oral prednisolone and nebulised salbutamol. Each child was considered fit for discharge when the PEFR was sustained at 75% or more of expected for height or, for children too young to use a peak flow meter, when wheezing, recession, and tachypnoea were absent. Prednisolone was then reduced over 3 or 4 days. Drug treatment was reviewed before discharge and altered if necessary and the children were regularly followed up in the outpatient clinic.

Statistics. The statistical method used for analysis of results was χ^2 test with Yates's correction for discontinuity.

Results

Age, sex, previous treatment. When compared with the overall population of children attending the outpatient asthma clinic (Table 1) there was no significant difference in the ages, sexes, or proportions of children admitted from the various treatment categories.

Month of admission. The admission rate each month was similar throughout the year. There were 33 admissions between April and September and 31 between October and March.

Mode of admission. Most (60%) children were admitted after being brought to casualty by their parents, some (20%) first saw their general practitioners, and the rest came either directly from the asthma clinic (11%) or from other hospitals (9%). 70% of admissions were clinic attenders and two-thirds of these came directly to casualty.

Previous admissions. 18% of children had never been in hospital before, 36% had had no admissions in the previous year, 32% had had one or two admissions, and 14% had more than two admissions in the previous year.

Precipitating factors. Seven admissions followed an emotional upset at school or at home and 2 followed physical exercise. Three children had been participating in a drug trial and were admitted during the period they were receiving a placebo. One child had erythema multiforme. The precipitating factors for the rest of the admissions could not be defined at the time the children arrived at hospital.

Drugs in the 12 hours before admission. Seven children had had no drugs before admission. Six were undiagnosed asthmatics and one had run out of bronchodilators. The 6 children referred from other hospitals were receiving aminophylline and hydrocortisone, but the theophylline levels on admission in these children were without exception below the lower limit of the accepted therapeutic range (10–20 μg/ml). Either orciprenaline, subcutaneous adrenaline, terbutaline, or aminophylline by suppository had been given to each of 4 other children. The remaining children all had had 1–4 doses of salbutamol in addition to whatever other daily treatment they were receiving, either cromoglycate, beclomethasone, theophylline, or corticosteroids.

Severity of attack on admission. Arterial blood-gases were measured in 38 admissions, 9 of whom were breathing increased fractional inspired oxygen (F_{IO_2}). PEFR measurements were made in 53 admissions. The relationships between the Pa_{O_2} measurements breathing air, the Pa_{CO_2} measurements, the PEFR measurements, and the clinical score are shown in Table 4.

There was no correlation between the magnitude of Pa_{O_2} breathing air and the clinical score. All children with Pa_{CO_2} measurements of $>6\cdot0$ kPa (>45 mmHg) had clinical scores of at least 6 compared with 22 of 30 with Pa_{CO_2} measurements of $<6\cdot0$ kPa ($\chi^2 = 4\cdot5$; $P<0\cdot05$). 13 of 24 children under 5 years and 25 of those older than 5 years had blood-gas analyses ($\chi^2 = 0\cdot43$; P = NS). Of those in whom measurements were taken, the younger group had higher Pa_{CO_2} values (Table 5). Children with pulsus paradoxicus of >25 mmHg tended to have Pa_{CO_2} values >5 kPa ($>37\cdot6$ mmHg) (Table 6) although this did not reach significance. Ten of 11 children who had PEFR measurements of $>25\%$ expected for height had clinical scores of 5 or less compared with only 6 of 42 with PEFR measurements $<25\%$ expected ($\chi^2 = 20\cdot8$; $P = <0\cdot001$).

Table 4 *Blood-gases, PEFR measurements, and clinical score on admission*

	Clinical score		
	Good (*<3*)	*Moderate* (*4–7*)	*Severe* (*>8*)

There was no correlation between the length of symptoms before admission and $Paco_2$ or PEFR on admission.

Chest x-rays and viral studies. 53 admissions had chest *x*-rays taken and these were considered normal in 9. 28 had evidence of hyperinflation, 2 showed mediastinal emphysema, and 14 showed areas of abnormal shadowing. The presence of mediastinal emphysema did not influence the management and in neither child did it become worse although one child required intermittent positive pressure ventilation (IPPV).

Nasopharyngeal swabs for viral culture were collected from 37 admissions. Respiratory syncytial virus (RSV) was grown from one. Complement-fixation titres against respiratory viruses and *Mycoplasma pneumoniae* were measured in paired sera in 31 admissions. Three showed at least a 2-dilution rise in titre to RSV (the positive culture was from one of these) and 2 children had a similar rise to *Mycoplasma pneumoniae*. All 5 children had abnormal shadows on chest *x*-rays.

Response to treatment. 18 admissions admitted received the oral regimen of prednisolone and nebulised salbutamol. They included all 11 in whom the admission PEFR was >25% expected for height and 2 others who had recordable PEFRs of 15 and 20% expected. Five other children in this group were too young to use the peak flow meter but 4 of them had clinical scores of <5 and the other had normal blood-gases.

The intravenous regimen was given to 46 admissions. This was continued for <12 hours in 12, 12–24 hours in 21, and >24 hours in 8. 14 children received either ampicillin or erythromycin. The time taken to be fit for discharge is shown in Table 7. Two children were discharged before their PEFR measurements were satisfactory and one returned 6 days later with continued wheezing. Most (73%) children were fit for discharge in 4 days or less.

There was no statistical correlation between either the length of symptoms before admission, the admission $Paco_2$ or the admission PEFR, and the time it took to be fit for discharge. 11 of 15 children with abnormal admission chest *x*-rays took at least 4 days to be fit for discharge compared with 7 of 37 with normal or hyperinflated chest *x*-rays ($\chi^2 = 11\cdot7$; P = <0·001). (The other child who had an abnormal chest *x*-ray was discharged before his PEFR was satisfactory.)

One child required IPPV. He had been transferred from another hospital where he had had a rising Pco_2 over 24 hours. The main difference in treatment was that he had not received aminophylline until just before transfer. The Pco_2 on admission to this hospital was 9·6 kPa (72 mmHg). An initial fall in Pco_2 was not sustained and IPPV was necessary for 40 hours. He made an uneventful recovery. No other child was shown to have a rise in $Paco_2$ after admission.

The child who was admitted on 8 occasions was a 13-year-old boy who until the summer before the period of this study had been fairly well controlled at boarding school on beclomethasone. After the

<4	42	5
5–7	9	4
>7		2

*Two children discharged before PEFR 75% expected.

holidays he did not want to return to school and remained at home. He was admitted on each occasion with a Pco$_2$ of >7 kPa ($>52 \cdot 6$ mmHg) but he always responded rapidly to the intravenous regimen. It was, however, known that his early morning PEFR was often low in spite of receiving adequate doses of theophylline, corticosteroids every other day, and salbutamol. In spite of supervision this boy was never satisfactorily controlled and he did not return to boarding school. After the study had ended, he arrived dead in casualty one morning after an acute attack of about 9 hours' duration.

Complications of therapy. One child suffered tremulousness after nebulised salbutamol. Five children became nauseated for about 30 minutes after the bolus dose of aminophylline. Injection of salbutamol intravenously was in most cases followed by a sustained mean increase in heart rate above that measured at the time of admission of 5–10 beats/min.

Change of outpatient drug regimen. After reviewing management, the outpatient treatment was changed before discharge in 34 instances either from intermittent bronchodilator therapy to continuous theophylline or cromoglycate, or from theophylline or cromoglycate to beclomethasone.

Follow-up. Of the 50 children studied, 48 were available for review 6 months after their first admission during the period of the study. 34 had no further admissions and were well controlled. Seven children had had one further admission, 6 children had had 2 further admissions, and one child (the boy described above) had had 8 admissions during the year of the study. Of these 14 who were readmitted, 5 were known to comply poorly with treatment at home and one was subsequently shown to have aspergillosis.

Discussion

After the epidemic of deaths from asthma during the 'sixties (Speizer *et al.*, 1968a, b; Inman and Adelstein, 1969; Fraser *et al.*, 1971) there was an acute awareness of the need for earlier recognition and more aggressive treatment of acute severe asthma. Crompton and Grant (1975) emphasised the need for prompt admission to hospital for asthmatics, and an emergency service was set up in Edinburgh for this. The Hammersmith Hospital has operated an open admission policy for asthmatic children for several years. Parents are advised to seek medical help early if their child becomes acutely wheezy. Most children in this study were clinic attenders and many either had come straight to casualty, often after a phone-call to the hospital, or had made an emergency appointment at the clinic from where they were admitted. The criterion for admission to hospital was the failure to respond to two doses of bronchodilator 4 hours apart, and this may seem to be a low threshold. Nevertheless at least one-third of the 64 children had admission Pco$_2$ measurements of >5 kPa and in 24 of 53 admissions who could use a peak flow meter the measurement was unrecordably low. We think that our criterion for the diagnosis of 'status asthmaticus', and hence admission to hospital, was reasonable.

There was no seasonal variation in admission rate and children belonging to different treatment categories were just as likely to have an acute episode. Most admissions were within the first 48 hours of the start of cough or wheeze but there were a significant number who waited longer before seeking help. The deaths of young asthmatics are thought to be 'sudden and unexpected' (Speizer *et al.*, 1968b). This study shows that the blood–gas analyses and PEFR measurements on children admitted early in their attack are not much different from those admitted later. It may be argued that had an open admission policy not been in operation the early admissions may have stayed longer at home with a less favourable outcome.

The precipitating factor for each admission was difficult to evaluate. Only 16% of children investigated were shown to have an associated viral or mycoplasmal infection. Mitchell *et al.* (1976) found a similar incidence of serological evidence of viral infection in a group of children with wheezy bronchitis and asthma but had more success in isolating the viruses. The methods for collecting and transporting swabs in this study may not always have been satisfactory.

The relationship between the clinical score and the admission Pco$_2$ was barely significant and neither was the presence of pulsus paradoxicus helpful in predicting hypercapnoea. We suggest therefore that, in all but the slightest attacks, the measurement of arterial blood–gases is the only satisfactory method to assess the severity of physiological disturbance in status asthmaticus. Commey and Levison (1976) suggested that sternocleidomastoid contraction and supraclavicular recession are useful signs of severity but their absence does not mean that severe airways obstruction is not present. Similarly, although Galant *et al.* (1978) were able to relate the magnitude of pulsus paradoxicus to other parameters of respiratory function, such as PEFR, the absence of large paradox did not mean that severe airways obstruction did not exist.

Young children were much more severely ill on admission as judged by blood–gas analysis than

LIBRARY

older ones. Six of 8 deaths reported by Buranakul *et al.* (1974) were in children aged 3 years or less and 6 of 13 children in respiratory failure reported by Simons *et al.* (1977) were under age 3 years. Particular attention should therefore be paid to the evaluation of status asthmaticus in young children.

PEFR measurements are useful in following progress after admission to hospital and, in this study, the admission PEFR was also useful in predicting those children who were likely to respond favourably to oral corticosteroids and nebulised salbutamol alone. It may be that those children who can record a PEFR of >25% expected for height could be satisfactorily managed at home either after nebulised salbutamol given in casualty or IM salbutamol given at home together with a short course of prednisolone.

The treatment outlined in this paper resulted in a rapid and sustained improvement in PEFR and was relatively free from side effects. Most children were fit for discharge and return to school within 4 days. Only one child needed IPPV. No other child had a rise in Pco_2, not even those receiving increased F_Io_2. Children with abnormal chest *x*-rays took longer to recover and all five with proved viral or mycoplasma infection took over 4 days to recover. We suggest that if an antibiotic is to be used in asthmatic children, erythromycin is a suitable choice as it will treat *Mycoplasma pneumoniae* and many of the bacteria pathogenic to the respiratory tract.

Gregg (1975) stated that 'Every attack of severe asthma should be regarded as a failure in (his) previous medical care . . .'. In this study over half the children required a change in treatment after their outpatient control had been reviewed. This emphasises the need for regular follow-up of all childhood asthmatics and the need to educate parents to seek help if their children's symptoms increase in frequency.

We suggest that all children presenting in status asthmaticus with a PEFR of <25% expected for height should be admitted to hospital and should be treated with IV aminophylline and hydrocortisone in addition to nebulised salbutamol. They should be considered fit for discharge when PEFR measurements are sustained at 75% expected for height. Young children should, of course, be accompanied by an adult. This practice may not only reduce the mortality due to asthma but also the need for IPPV and will ensure a rapid return to school and normal activity.

We thank Mr. A. Holly for carrying out the viral studies.

Role of viruses and bacteria in acute wheezy bronchitis in childhood: a study of sputum

MARY E. C. HORN, SYLVIA E. REED, AND PAUL TAYLOR

Department of Microbiology, Brompton Hospital, and Medical Research Council Common Cold Unit, Harvard Hospital, Salisbury, Wiltshire

SUMMARY Sputum, nasal swabs, and throat swabs were obtained from 22 children aged between 5 and 15 years during 72 attacks of wheezy bronchitis. A virus, most commonly a rhinovirus, was isolated in 49% of all episodes and in 64% of 22 severe episodes requiring treatment with corticosteroids; the isolation rate was higher early in the illness than later. Virus was recovered more often from sputum than from the nose or throat, suggesting that viral replication occurs freely in the lower respiratory tract: the cytological findings in sputum were compatible with an inflammatory response to viral infection. Pathogenic bacteria appeared to play a minor role compared with viruses, and routine antibiotic treatment was probably of little value in most cases. The significance of the results is discussed in relation to the pathogenesis of childhood wheezy bronchitis.

Wheezy bronchitis of childhood may be defined as an acute illness usually preceded by upper respiratory symptoms and characterised by cough and variable degrees of wheezing, breathlessness, and mucus expectoration. On auscultation high-pitched wheeze is audible over most parts of the chest in addition to medium crepitations or rhonchi. Various terms such as 'asthmatic bronchitis', 'exacerbations of asthma', or 'bronchitis with bronchospasm' have been used to describe this illness. Several studies have established that during these episodes common respiratory viruses can be isolated from the upper respiratory tract (McIntosh *et al.*, 1973; Minor *et al.*, 1974; Horn *et al.*, 1975; Mitchell *et al.*, 1976). Horn and Gregg (1973) and Horn *et al.* (1979) noted that certain children experience recurrent episodes of wheezy bronchitis and it seems clear that undetermined constitutional factors must influence the individual child's response to infection with common respiratory viruses. The pathogenic mechanisms underlying the cough, bronchoconstriction, and excess lower respiratory secretion that characterise this condition are unknown. It is possible either that the lower respiratory symptoms are a remote response to viral infection in the upper respiratory tract, or that they are a consequence of viral invasion of the bronchial mucosa.

We now describe a study designed to provide further evidence on this point. Sputum collected from children during attacks of wheezy bronchitis was examined in parallel with nasal and throat swabs using virological, bacteriological, and cytological techniques.

Patients and methods

Clinical methods. The study was carried out in a special asthma and bronchitis clinic held twice weekly for children in a general practice. Between October 1974 and April 1976 (excluding July and August 1975) each child attending for treatment of an episode of wheezy bronchitis, as defined above, was accepted for study provided he presented within 5 days of onset of the initial symptoms (upper or lower respiratory) and was able to expectorate sputum. 22 children (15 boys and 7 girls), aged between 5 and 15 years, satisfied these conditions; all had a history of recurrent wheezy bronchitis and were among those previously investigated by Horn *et al.* (1975). The number of episodes investigated per child ranged from one to 15. 19 of the 22 children wheezed on exercise, on exposure to inhaled allergens, or with emotional upsets; the remaining 3 wheezed only during attacks of wheezy bronchitis. 17 of the 22 children gave positive reactions to at

P. TAYLOR, chief medical laboratory scientific officer

least one of 14 inhaled allergens used in skin prick tests. These children were defined as atopic and the remaining 5 as nonatopic; 3 of the nonatopic children were known to wheeze only during attacks of wheezy bronchitis. A family history of asthma or allergic rhinitis was present in 12 atopic children and 5 nonatopic ones; the remaining 5 children had no such family history but were atopic on prick testing.

Episodes were classified retrospectively according to severity on the basis of airflow obstruction and the need to give corticosteroids, judged clinically. Airflow obstruction was measured by the fall in peak expiratory flow (PEF) rate, expressed as a percentage of the predicted PEF for height (Godfrey *et al.*, 1970). Episodes were classified as severe if treatment with corticosteroids was required for control or if the fall in PEF was at least 60%; moderate episodes were those which did not require corticosteroids and in which PEF fell by 40–59%; mild episodes were those in which the PEF fell by less than 40%.

Appropriate bronchodilator or corticosteroid treatment was prescribed during the acute phase of the illness until prophylaxis with an oral bronchodilator and sodium cromoglycate or beclomethasone dipropionate aerosol could be resumed. Physiotherapy was an integral part of treatment and sputum samples were obtained by encouraging coughing during postural drainage and percussion.

As controls, 31 nasal and throat swabs collected from 17 children between acute attacks were also examined virologically, but control sputum samples could not be obtained.

The first sputum samples, nasal swabs, and throat swabs examined in each episode were collected at the child's first attendance, within 5 days of onset of respiratory symptoms, and before prescribing antibiotics or corticosteroids. Whenever possible a second nasal swab and sputum sample were obtained later in the illness, generally within 5 days of the first. If bacterial infection was thought likely on clinical grounds, penicillin, co-trimoxazole, or ampicillin (in order of frequency) was prescribed when the child first attended the clinic. One of these was prescribed at the second visit, after second samples had been collected, if the first samples had shown *Streptococcus pyogenes* in the throat or if there had been any pathogenic bacteria in the sputum and the clinical condition still warranted treatment.

Specimens for virological examination were kept chilled in transport medium and delivered to the laboratory within 4 hours. Throat swabs transported in Stewart's medium and sputum samples were examined bacteriologically, and the sputum was also examined cytologically.

Laboratory methods. The techniques for isolating viruses and *Mycoplasma pneumoniae* were as previously described (Horn *et al.*, 1975), except that MRC-5 human embryo lung fibroblasts were substituted for WI-38 cells which were no longer obtainable. After inoculation into standard cultures, the remainder of each specimen was stored at -70°C and later cultured in rhinovirus-sensitive HeLa cells (Strizova *et al.*, 1974). Rhinoviruses were characterised by their typical cytopathic effect (cpe) and by their acid lability, but were not serotyped. No attempt was made to quantitate rhinovirus by titration, but the relative amount of virus present in the various types of specimens was assessed roughly by noting the day of development of rhinovirus cpe in the culture and calculating the means for nasal swabs and sputum samples. Organ cultures or other special techniques for isolation of coronaviruses were not used.

Throat swabs were cultured on blood agar and MacConkey agar incubated aerobically at 37°C. Sputum was homogenised with pancreatin, shaken, and similarly cultured undiluted, and at a dilution of 10^{-4}. Isolations of *Streptococcus pneumoniae* and *Haemophilus influenzae* were considered significant if the organisms were detected at a dilution of 10^{-4}: *Staphylococcus aureus* and *S. pyogenes* in any numbers were considered significant.

Sputum smears were stained with haematoxylin and carbol chromotrope 2R. The whole area of each specimen was examined by a single observer, and the prevalence of leucocytes, bronchial epithelial cells, and macrophages was estimated on an arbitrary scale 1+ to 3+. Eosinophils were assessed as an approximated percentage of the total cellular content: an arbitrary figure of at least 25% eosinophilia was considered abnormal, as were bronchial epithelial cells or macrophages scored as 1+ or more and leucocytes as 2+ or more.

Results

72 episodes of wheezy bronchitis were studied, of which 18 were classified as mild, 24 as moderate, and 30 as severe. Upper respiratory symptoms were present in all but one moderately severe episode. Rhinorrhoea was present in 71 episodes, pharyngitis in 39, otitis media in 2, sinusitis in 2, pyrexia in 11, headache in 8, and myalgia in 2. Sputum samples were obtained at the first attendance in all but 2 episodes in which severe bronchospasm prevented expectoration; in these 2, sputum was obtained at the second attendance. In a few episodes nasal or throat swabs could not be obtained. Second samples were obtained in 54 episodes: 42 within 5 days of the first, 11 within 8 days, and one after 15 days.

Virology. One or more viruses were isolated in 35 (49%) of the 72 episodes. The virus isolation rates in mild, moderate, and severe episodes were 17, 54, and 63% respectively, and in 22 severe episodes requiring corticosteroid treatment the recovery rate was 64%. Table 1 shows the number of episodes yielding virus, with its source, and the Figure gives the rate of virus isolation for each category of specimen. Rhinoviruses predominated over all other agents and were recovered throughout the study. Influenza viruses were isolated only during the two main epidemic periods, December 1974 to January 1975 (influenza A), and January to March 1976 (influenza A and B). Of the 30 severe episodes investigated, 12 were associated with rhinovirus alone or in combination with another agent, and 4 with influenza viruses.

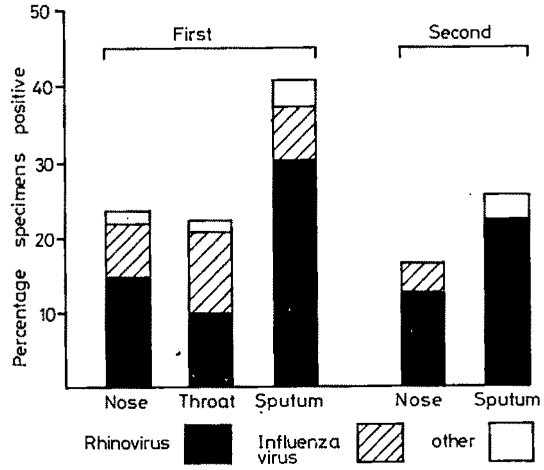

Figure *Rates of isolation of rhinovirus, influenza virus, and other viruses (including M. pneumoniae) from various specimens.*

The first sputum samples were the best source of virus, particularly rhinovirus: influenza viruses were more common in nasal and throat swabs than in sputum (Figure). 29 (41%) isolates were obtained from 70 first sputum samples, 15 (23%) from 64 first nasal swabs, and 14 (22%) from 64 throat swabs. The overall isolation rate from first sputum samples was therefore significantly higher than from the first nasal or throat swabs ($P<0\cdot05$, χ^2 test). The mean day of development of rhinovirus cpe in HeLa cells was 3·9 days for first sputum samples and 4·6 days for first nasal swabs, and in MRC-5 cells the corresponding figures were 5·1 and 8·0 days, indicating that the sputum probably contained more virus than the nasal swabs. The second samples, taken later in the illness, gave fewer isolates than the first, but again sputum showed more isolates than the nose. In only 3 episodes were second samples positive when first samples had been negative.

Only one of the 31 control swabs from the upper respiratory tract contained virus.

Bacteriology. 28 (39%) of the 72 episodes showed significant bacterial isolations but, in 15 of these, the isolations were from throat swabs; only 3 sputum samples contained the same organism as was found in the throat swab. Only 12 (17%) of 70 first sputum samples gave significant bacterial isolations (Table 2), and the episodes from which these samples were obtained were not distinguishable by any particular clinical feature. The bacteria isolated from sputum in 6 virus-positive episodes

Total	19	(27)	12	(17)	3	(6)

were similar to those recovered in 7 virus-negative episodes. There was no clear association between individual viruses and bacteria except perhaps in the case of influenza virus; in 3 of the 7 episodes in which influenza was the only virus found, bacteria were present in sputum (*S. aureus* twice and *S. pneumoniae* once), compared with isolation of bacteria from sputum in only 3 out of 20 episodes showing rhinovirus (*S. aureus*, *H. influenzae*, and *S. pneumoniae*, each once). There was no clear correlation between the bacterial isolation rate from first sputum specimens and the severity of illness, the rates in mild, moderate, and severe episodes being respectively 1 (6%) of 18, 7 (29%) of 24, and 4 (13%) of 30. In 38 episodes in which pharyngitis occurred and throat swabs were cultured, 13 (34%) of these swabs showed pathogenic bacteria (*S. pyogenes* 7 times and *S. aureus* 6 times). Seven of the 11 febrile children had bacterial infections. Both cases of sinusitis were associated with *S. pyogenes* and one of the two cases of otitis media showed *S. pneumoniae*.

Antibacterial agents were prescribed at the time of the first visit in 30 episodes but the cultures subsequently showed that bacterial infection had been present in only 9 of these episodes, 5 of the relevant first sputum samples being positive, and 7 of the throat swabs. No initial antibacterial therapy was given in 42 episodes, and only one second sample from these episodes contained bacteria (*S. aureus*) which had not been present in the first sample. Both first and second sputum samples were examined bacteriologically in 50 episodes of which 22 were treated with antibiotics at the time of the first visit and 28 were not. The bacterial isolation rate from first sputum samples was 14% in both the treated and the untreated group. In the second samples the rates fell in both groups, to 5 and 7% respectively.

Cytology. The cells classified as macrophages contained foamy and particulate material and were considered by the cytologist to be alveolar in origin. The relative frequency of the various cell types appeared to be little influenced by the agent isolated (Table 3) and there was no significant correlation between any of the cytological findings and severity. Bronchial epithelial cells in second sputum samples were more common in 'bacteria-positive' than in 'bacteria-negative' episodes, but numbers were small and the differences not significant. Both leucocytosis and eosinophilia graded as significant were less common in second samples than in first, and the decrease in eosinophils occurred both in the presence and absence of corticosteroid treatment. In 48 episodes both first and second sputum samples were examined cytologically. In 21 such episodes initially treated with antibiotics, 81% of first samples showed leucocytosis compared with 33% of second samples (and this difference was significant, $P<0\cdot01$, χ^2 test). In 27 episodes not treated with antibiotics the rates in first and second samples were 74 and 52% respectively ($P>0\cdot05$, χ^2 test).

*Defined in Methods, †virus recovered from one or more of the specimens originating in the episode, ‡significant isolation of bacteria from either first or second sputum specimen from the episode.

Atopy. 14 episodes in the 5 nonatopic children were compared with 58 in the 17 atopic children. Significant eosinophilia in sputum was less common in the nonatopic children (43% of 14 episodes) than in the atopic group (78% of 58 episodes); the virus isolation rate was higher in the nonatopic (71% of 14 episodes) than in the atopic children (43% of 58 episodes). Both of these differences were significant ($P < 0{\cdot}05$, χ^2 test) although the statistical comparison was somewhat unsatisfactory as one atopic child contributed 9 episodes and one, who was nonatopic, contributed 15. The individual virus isolation rates in these 2 children were 7 (78%) of 9 episodes in the nonatopic child and 6 (40%) of 15 episodes in the atopic child. The serum immunoglobulin A of each of these children was at the lower limit of the normal range for his age.

Discussion

Eadie *et al.* (1966), Stenhouse (1967), and Stott *et al.* (1968) found that rhinoviruses could be isolated from sputum of bronchitic adults, sometimes in high titre. Lambert and Stern (1972) cultured sputum and nasal and throat swabs from two asthmatic subjects, one of whom was a child, and recovered virus in 5 of 11 exacerbations. In the present study of wheezy bronchitis of childhood a virus was isolated from 49% of episodes, and the sputum samples collected within 5 days of onset of symptoms gave a virus isolation rate of 41%. These figures are probably an underestimate of the true incidence of viral infection as our techniques may have failed to detect some rhinovirus strains, which are particularly difficult to cultivate, as well as coronaviruses. The latter are known to be important in this condition (McIntosh *et al.*, 1973).

In previous studies, Horn *et al.* (1975, 1979) showed that rhinoviruses were the agents most often isolated from the upper respiratory tract during attacks of wheezy bronchitis; in the present study these viruses were found even more commonly in sputum, especially in severe episodes. Although the volume of sputum cultured for virus was probably greater than the volume of nasal secretions, the frequency of isolation of rhinovirus from sputum and the speed with which the cpe developed in the cultures strongly suggested that more virus was present in the lower than in the upper respiratory tract and that its detection in sputum was not simply due to contamination with upper respiratory secretions. As in earlier studies (Horn *et al.*, 1975, 1979) influenza virus was found relatively rarely (in 9 of 72 episodes), although the frequency will naturally depend in part on the epidemic prevalence of influenza at the time of study. It remains uncertain whether influenza viruses have less propensity for causing wheeze than rhinoviruses.

There was little evidence to suggest that bacterial infection was a frequent initiating cause of wheezy bronchitis. Pathogenic bacteria were found in 27% of throat swabs, but the same organisms were rarely found in sputum. The clinical suspicion of bacterial infection raised in a proportion of the episodes by severe pharyngitis, high pyrexia, or otitis media was confirmed by bacteriological tests in about half the cases; secondary bacterial infection was uncommon regardless of antibiotic treatment. The results gave little justification for the use of routine antibacterial treatment in the absence of specific indications, although it was noted that the decrease in leucocytosis in second sputum samples was more pronounced in antibiotic-treated than in untreated episodes.

Our evidence shows that virus infects the lower as well as the upper respiratory tract in many episodes of wheezy bronchitis. The bronchial epithelial cells and inflammatory cells found in sputum confirm that the lower respiratory tract is infected, and the evidence therefore suggests that the bronchoconstriction occurring in wheezy bronchitis is produced by mechanisms initiated locally. It is not known whether rhinovirus infection in normal children extends to the lower airways although the symptoms to which it gives rise are confined to the upper respiratory tract. Direct evidence is impossible to obtain because sputum is not produced by normal children. Indirect evidence suggests that viral invasion may occur in the absence of lower respiratory symptoms, since Cate *et al.* (1973), Fridy *et al.* (1974), Blair *et al.* (1976), and Hall *et al.* (1976) all showed minor abnormalities of peripheral airways function in normal adults with colds. The abnormality of the child who develops wheezy bronchitis during virus infection may therefore be associated not so much with the presence of virus in the lower respiratory tract as with its excessive replication there and the effect of this on his already increased liability to bronchoconstriction. This view is compatible with the findings of Empey *et al.* (1976), who showed that the bronchoconstrictor response to histamine in normal subjects with colds was greater than in those without. These authors suggested that the response of the asthmatic, whose airways epithelial receptors are already sensitised, is an exaggeration of the normal.

Allergic factors may clearly also be relevant to the aetiology of childhood wheezy bronchitis; many of the patients are atopic and the present study shows that viral infection is often associated with sputum eosinophilia. A link between mechanisms of allergy and viral infection, at least in atopic subjects, has been given by Ida *et al.* (1977) who showed that incubation of human leucocytes with virus *in vitro* enhanced their release of histamine when they were subsequently exposed to ragweed antigen or anti-human IgE.

The findings in this study suggest that children subject to wheezy bronchitis may be regarded as abnormal not only in their exaggerated bronchoconstrictor response, but also in the profuseness of viral replication in the lower respiratory tract, with its accompanying inflammatory reaction. The reason for excessive virus growth at this site is not clear but may possibly be related to defects of immunity, such as local IgA deficiency. A study of immunoglobulins in sputum might be profitable when sufficiently standardised techniques become available.

We acknowledge generous grants to M.E.C.H. from the Board of Governors, Brompton Hospital, National Heart and Chest Hospitals. We thank Dr Ian Gregg for helpful criticism of the manuscript, Dr J. B. C. Evelegh, Dr A. G. Huff, and Dr. L. Burt of Roehampton, London, whose patients we studied, Mrs José Wilson for physiotherapy and collection of sputum samples, Miss D. Coombs for cytological studies, Mrs M. V. Chadwick for bacteriological investigations, and Mrs Pat Muir and Mr Arthur Miller for virological assistance.

Changing incidence of neonatal hypermethioninaemia: implications for the detection of homocystinuria

P. D. WHITEMAN, BARBARA E. CLAYTON, R. S. ERSSER, PAMELA LILLY, AND J. W. T. SEAKINS

Department of Chemical Pathology, The Hospital for Sick Children and Institute of Child Health, London

SUMMARY The Guthrie test was used to measure blood methionine concentrations in 670 764 neonates during the period from May 1970 to December 1977. Raised values (>4 mg/100 ml; 268 μmol/l) were found in 147 babies (6–14 days old) and 55 of these still had raised values when retested 2–6 weeks later. 48 infants had transient hypermethioninaemia of at least 3 weeks' duration, one had a more persistent form associated with abnormal liver function tests, 3 had different forms of homocystinuria, and one infant, who was asymptomatic at the time of detection, had hypermethioninaemia associated with a rapidly fatal form of tyrosinaemia (tyrosinosis). Two infants could not be followed up. Transient hypermethioninaemia has not been detected in this laboratory since 1975. There was a greatly reduced incidence of transient hypermethioninaemia in girls after 1972 and in boys after 1975; this may have been due to recent changes in infant feeding practices in the UK. Homocystinuria was last detected in this laboratory in 1972; the apparent change in incidence is significant ($P<0 \cdot 05$) and suggests that the diagnostic value of this screening procedure should be reassessed.

Neonatal screening for homocystinuria on a national scale is not yet acceptable because of the apparent low incidence of the disease, the uncertainty about the reliability of methods of screening, and about the long-term efficacy of current methods of treatment. Results from different screening centres suggest that the incidence of homocystinuria varies considerably from one area to another, but the extent to which this reflects a true difference in the incidence of the disease or a difference in methodology has been questioned (Thalhammer, 1975; Wilcken and Turner, 1978). Classical homocystinuria can be accompanied by hypermethioninaemia in the neonatal period (Komrower *et al.*, 1966) and this finding forms the basis of one simple screening procedure (Guthrie, 1968). However, hypermethioninaemia does not occur in variant forms of homocystinuria associated with defects in the biosynthesis of folate coenzymes (Mudd *et al.*, 1970, 1972) and may sometimes be absent in classical homocystinuria in the first days of life (Komrower *et al.*, 1966; Levy *et al.*, 1971).

Transient hypermethioninaemia in the neonatal period has been associated with a high protein intake and, in premature infants at least, a low hepatic cystathioninase activity may be a contributory factor (Levy *et al.*, 1969; Sturman *et al.*, 1970). Hypermethioninaemia may also be found in some forms of tyrosinaemia (Scriver *et al.*, 1966), in severe liver disease (Walshe, 1953; Iber *et al.*, 1957), and in association with a deficiency of hepatic S-adenosylmethionine synthetase activity (Gout *et al.*, 1977).

In 1970, the screening programme for phenylketonuria at this hospital was extended to include the detection of homocystinuria in the newborn by measuring blood methionine concentrations. The results of this additional study are presented in this report.

Methods

The sample. Since May 1970 the neonatal screening laboratory at this hospital has screened all babies born in an area corresponding to that now under the

auspices of the North-east and North-west Thames Regional Health Authorities. When the National Health Service was reorganised in 1974 the area from which patients were drawn changed slightly; small parts of Buckinghamshire and Berkshire were then excluded.

Collection of specimens. On or after the 6th day of life and in most instances up to the 14th day, midwives or health visitors collected blood, obtained by heel prick, on to absorbent cards (supplied by the Department of Health and Social Security; Code no. HMR 101/6) which were then posted to the laboratory in protective plastic covers.

Blood methionine assay. The method was basically that of Guthrie (1968). Dried blood spots of 6·4 mm in diameter were punched out of the cards and placed on the surface of an agar plate containing the inhibitor methionine sulphoximine and spores of *Bacillus subtilis* (strain ATCC-6633). Standard controls which consisted of expired donor bloods containing a range of L-methionine concentrations (1–20 mg/100 ml; 67–1342 μmol/l) were also included on the plate. Plates were incubated overnight at 37°C. The inhibitor suppresses growth of *B. subtilis* unless methionine is present in sufficient concentrations. The methionine concentration in the blood sample was determined by comparing the diameter of the growth zone near the blood spot with that of standard controls.

Other laboratory investigations. Amino-acids were eluted from blood spots with ethanol (70% by vol. in water), separated by thin-layer chromatography and located on separate layers with ninhydrin and iodoplatinate reagents (Ersser and Smith, 1976). Amino-acids in plasma and urine were analysed by both thin-layer and quantitative ion-exchange chromatography (Ersser, 1976).

Results and discussion

Overall findings. During a 7½-year period blood methionine concentrations were determined in 670 764 neonates. Raised values were initially detected in 147 infants and 55 of these still had raised blood methionine levels when retested 2–6 weeks later (Table 1). Of the babies who had abnormal blood methionine concentrations in the 2nd test, 3 had different forms of homocystinuria, one had a severe form of tyrosinaemia (tyrosinosis), one had hypermethioninaemia associated with abnormal liver function tests, and 48 had transient hypermethioninaemia which resolved uneventfully. The other 2 babies were not fully investigated; one went abroad and the other, who had transient hypermethioninaemia without homocystinuria, was admitted to another hospital with severe congenital abnormalities of the central nervous system.

*Began 11th May 1970.

Although initial tests were generally done on specimens obtained 6–14 days after birth, some specimens were not entirely satisfactory and repeat samples were needed before an accurate value could be obtained for a suspected abnormal blood methionine concentration. Since 1971, about 5% of all first specimens have been unsatisfactory.

Transient hypermethioninaemia. 48 of the 517 939 babies screened in the period 1970 to 1975 had a transient hypermethioninaemia of at least 3 weeks' duration but this resolved uneventfully in half of them by the 3rd month of life and in all of them by the 5th month. Several of these infants had very high protein intakes and in such cases mothers were advised to change to a milk with a lower protein content. None of the infants with transient hypermethionaemia was known to have been breast fed but our records on this point were unfortunately incomplete. One infant whose blood methionine concentration increased to 1342 μmol/l during a 3-month period was grossly overweight (height, 25th centile; weight, 90th centile); he had been weaned early and was receiving large amounts of protein (protein intake from milk alone was 5 g/kg per day). Appropriate adjustment of his diet was accompanied by a rapid reduction of blood methionine to a normal concentration.

Transient hypermethioninaemia was not detected in the 152 825 neonates screened in 1976 and 1977. There was a striking reduction in the incidence of transient hypermethioninaemia in the girls after 1972 ($P<0\cdot01$) and in the boys after 1975 ($P<0\cdot01$) (Figure). There were no obvious changes in methods of sample collection or analysis which could have

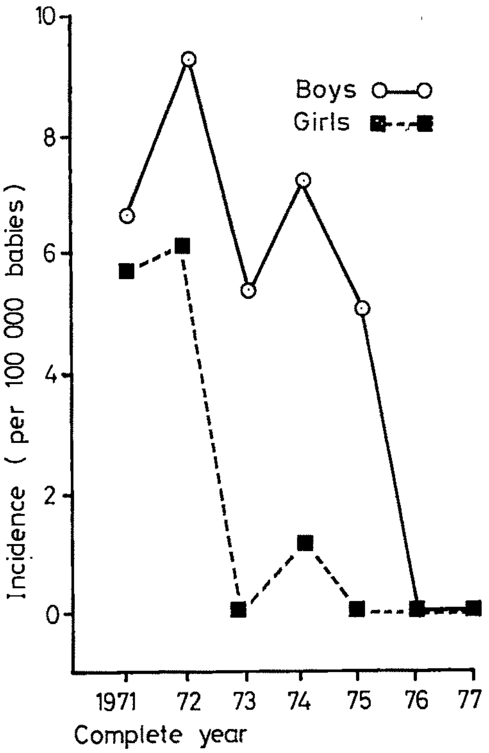

Figure *The incidence of transient hypermethioninaemia in baby boys and girls.*

accounted for this. The most likely explanation is the change in infant feeding practice which has taken place in the UK. A reduction in the protein content of infant milk formulae, later introduction of solids, and a renewal of interest in breast feeding may all have contributed.

The maximum blood methionine concentrations recorded in boys and girls with transient hypermethioninaemia were similar (boys: mean 12 mg/100 ml (805 μmol/l), gross range 5–20 mg/100 ml (336–1342 μmol/l); girls: mean 11 mg/100 ml (738 μmol/l), gross range 7–16 mg/100 ml (459–1072 μmol/l)). These maximum values tended to occur later in girls than in boys (girls: mean 45 days, gross range 21–87; boys: mean 30 days, gross range 6–75) but the difference was not significant. Differences in the periods between sampling in different individuals and the small number of affected infants suggest that this finding should be interpreted with caution.

Homocystinuria. During the first 3 years of the screening programme homocystinuria was confirmed in 3 infants (Table 2) giving an incidence of one in 88 987 during that period. One required treatment with a low methionine diet, one responded to treatment with pyridoxine, and the 3rd had a transient form which responded to a low-protein diet combined with pyridoxine supplement, and resolved within a year so that no further treatment was required. Table 2 compares the initial blood methionine concentrations in these patients. The infant with the pyridoxine-responsive form had lower initial blood methionine concentrations than the infant who responded only to diet. Levy *et al.* (1971) observed that an infant with the pyridoxine-responsive form had a normal blood methionine concentration at 4 days. Brenton and Cusworth (1971) found that clinical manifestations were less severe in the pyridoxine-responsive form.

No further cases of homocystinuria have been detected here since 1972; the change in incidence between the periods 1970–72 and 1973–77 is significant ($P<0\cdot05$).

Other conditions which were associated with hypermethioninaemia. A baby boy who was asymptomatic at the time of detection had hypermethioninaemia associated with an acute form of tyrosinaemia (tyrosinosis). The blood methionine concentration was only slightly raised at 6 days but had increased further by 3 weeks. Further investigations showed the presence of tyrosinaemia, tyrosyluria, and a proximal renal tubular defect. Failure to thrive, liver dysfunction, and defective blood coagulation soon became evident and despite attempts to control blood methionine and tyrosine concentrations the child died at 14 weeks. Gjessing and Halvorsen (1965) and Larochelle *et al.* (1967) concluded that the hypermethioninaemia which occurs in acute tyrosinosis is due to severe liver damage, but this was contested by Gaull *et al.* (1968) who suggested that an unidentified abnormality caused both the hypermethioninaemia and the tyrosinaemia. Linblad *et al.* (1977) suggested that some severe forms of hereditary tyrosinaemia may be associated with a fumarylacetoacetase deficiency and that the resulting metabolites, succinyl acetate and succinylacetone, are toxic to the liver and kidneys.

Another baby boy, born in 1970, had a raised blood methionine concentration (about 10 mg/100 ml; 671 μmol/l) and raised serum alkaline phosphatase, alanine transferase, and aspartate transferase activities which persisted into the 2nd year of life. No other biochemical abnormality was detected and unlike the otherwise similarly affected infants described by Komrower and Robins (1969) he was not anaemic. The child developed normally and the condition resolved spontaneously without treatment or change of diet.

Table 2 *Summary of findings in three patients with homocystinuria and a patient with a severe form of tyrosinosis*

Disease	*Sex*	*Year of detection*	*Blood methionine concentrations mg/100 ml (μmol/l)*		*Other laboratory findings*	*Treatment and outcome*
			Age (6–7 days)	*Age (3–4 weeks)*		
Homocystinuria responding only to diet	M	1970	20 (1342)	20 (1342)	*3 weeks* Plasma homocystine 0·25–0·5 mg/100 ml. Urine analysis: positive cyanide-nitroprusside test. Increased excretion of homocystine	*8 weeks* No response to pyridoxine. Biochemical response to low methionine diet *8 years* Clinically normal. Controlled by low methionine diet
Homocystinuria pyridoxine responsive	M	1971	12–15 (805–1007)	15 (1007)	*3 months* Plasma methionine >20 mg/100 ml, homocystine 0·78 mg/100 ml Urine analysis: weakly positive cyanide-nitroprusside test. Increased excretion of homocystine	*3 months* Responded to low protein diet. *6 months* Responded to pyridoxine 250 mg twice daily. *7 years* Controlled with pyridoxine. No clinical manifestations of homocystinuria. History of asthma and chest infections. Cysts in right upper lobe—cause unknown.
Homocystinuria transient	F	1972	10–12 (671–805)	20 (1342)	*6 weeks* Urine analysis: intermittently positive cyanide-nitroprusside test	*8 weeks* Responded to low protein diet and pyridoxine *1 year* Blood methionine normal on normal diet and without pyridoxine supplements *5 years* Clinically and biochemically normal
Tyrosinosis (tyrosinaemia)	M	1976	4 (268)	11 (738)	*3 weeks* Plasma tyrosine 800 μmol/l *5–6 weeks* Serum phosphate 0·88 mmol/l, calcium 2·15 mmol/l, alkaline phosphatase 1079 IU/l. Urine analysis: aminoaciduria (generalised), glucosuria, tyrosyluria. Megaloblastic anaemia. Abnormal clotting function	Treatment with a diet low in methionine, phenylalanine, and tyrosine produced a rapid reduction in plasma tyrosine but raised plasma methionine persisted. The child developed hepatosplenomegaly with ascites and died at 3 months after pulmonary haemorrhage. Early cirrhosis of the liver was present

Discussion and conclusions

During the early years of the neonatal screening programme at this hospital most bottle-fed infants in the UK were receiving cows' milk preparations with a high protein content (giving neonates about 5 g protein/kg per day) and many of these infants were also receiving solid foods by 4 weeks (Black, 1971; Shukla *et al.*, 1972; Davies, 1973). The association of neonatal hypermethioninaemia with a high protein intake had already been recognised (Komrower and Robins, 1969), and Sturman *et al.* (1970) suggested that the high methionine:cystine ratio of the protein in cows' milk was inappropriate for human infants. Reports on the possible harmful effects of infantile overnutrition (Taitz, 1971; Menkes *et al.*, 1972; Shukla *et al.*, 1972) may have influenced such feeding practices as the early introduction of solid foods, and may have contributed to the initial reduction in the incidence of neonatal hypermethioninaemia in 1973. Several 'modified' milks with protein concentrations of 1·8 g per 100 ml were introduced in 1973 and 1974. Also in the period from about 1970 to 1972, maternity units began to use infant milk formulae which were accurately diluted and prepacked by the manufacturers.

The apparent disappearance of transient neonatal hypermethioninaemia in 1976 may have been due to the withdrawal of high-protein milks—such as national dried full cream milk—the widespread introduction of infant milk preparations with a protein content and casein:lactalbumin ratio approaching that of human breast milk, and to the publication *Present-day Practice in Infant Feeding* (Department of Health and Social Security, 1974) which put forward official recommendations for changes in infant feeding practice. The reason why the girls but not the boys responded as early as 1973 is uncertain but could be due to a difference in ability to metabolise methionine or to a difference in total milk intake. Whatever the cause these results suggest that the protein intake, or more specifically the methionine intake, of infants decreased in 1973 and decreased further in 1976.

The apparent failure to detect homocystinuria since 1972 coincided with the reduction in the incidence of neonatal hypermethioninaemia. No 'missed' cases of homocystinuria in the areas concerned have yet been brought to our notice but the disease may not be obvious in the early stages. Thus, it appears that the earlier moves away from breast feeding (Newson and Newson, 1962) and the tendency towards infantile overnutrition were conducive to the detection of homocystinuria by neonatal screening programmes which measured blood methionine concentration in early infancy. Ironically, better infant feeding practices necessitate a reassessment of the methods used to detect homocystinuria. Furthermore possible similar effects on the neonatal screening of other inborn errors of amino-acid metabolism should be borne in mind.

These findings, and the studies of Wilcken and Turner (1978) in New South Wales, suggest that the true rate of homocystinuria is greater than that indicated by neonatal screening programmes. Infants with mild forms of the disease are even less likely to be detected. Estimates of the incidence of homocystinuria have varied widely from one area to another. This could be partly attributed to different methods of screening and to different patterns of infant feeding. At present there is no justification for national screening of homocystinuria early in the neonatal period and the reliability of the Guthrie method needs to be carefully reassessed.

The concentration of methionine in blood is normally <67 μmol/l and the cut-off point of 268 μmol/l used in the screening programme may now be too high. During a trial period, initially for one year, all infants screened at this centre who have blood methionine concentrations of 2 mg/100 ml (134 μmol/l) or more will be further investigated. However, recent experience suggests that this procedure will not improve the detection of homocystinuria. Furthermore, Wilcken and Turner (1978) suggest that even including a test for urinary homocystine in a neonatal screening programme at 6 weeks does not ensure detection of the disease.

We gratefully acknowledge the advice and help given by Dr D. Brenton, Dr Sylvia Darke, Miss Dorothy Francis, Mr R. A. Hendey, Dr A. D. Patrick, and Mrs Jean Shepherd.

Correspondence to Dr P. D. Whiteman, Wellcome Research Laboratories, Langley Court, Beckenham, Kent.

Received 24 October 1978

Dr I. B. Sardharwalla of the Willink Biochemical Genetics Unit, Royal Manchester Children's Hospital, was invited to comment:

Our own experience is similar to that described by Whiteman *et al.* Most infants in the North-western Region are tested between 10 and 14 days after birth (primarily for phenylketonuria) and to date over half a million babies have been screened. The method used is one-dimensional paper chromatography of plasma (Scriver *et al.*, 1964) which can detect 6 related amino-acid abnormalities, including hypermethioninaemia (Sardharwalla *et al.*, 1972). This technique is sufficiently sensitive to detect a plasma methionine concentration of 0·2 mmol/l (2·98 mg/100 ml). If plasma methionine concentration is >0·6 mmol/l (>8·9 mg/100 ml) immediate steps are taken to have the baby brought to the metabolic unit for detailed investigations. If, however, on initial screening the plasma methionine is between 0·2 and 0·6 mmol/l the test is repeated after one month. If the repeat test shows a normal pattern no further action is taken, but a persistent abnormality is investigated.

Of 12 babies identified because initial levels of plasma methionine were >0·6 mmol/l, homocystinuria was confirmed in 5 of them, one had galactosaemia with liver damage, one had α-1-antitrypsin deficiency with liver involvement, and one was found to have bacterial hepatitis after septicaemia. In the other 4 babies in whom raised methionine was associated with raised plasma tyrosine we were able to establish the diagnosis of hereditary tyrosinaemia.

I share the view that some infants with homocystinuria will not be identified by any neonatal screening method designed to detect raised plasma methionine. One baby with homocystinuria, a younger sibling of a known case, did not have a raised level of plasma methionine when tested on the 10th and 17th days after birth, but the level of homocystine in the blood was increased when measured on day 17.

We too have noticed a steady fall in the incidence of transient hypermethioninaemia since 1973 and have seen this trend reflected in the incidence of the other aminoacidaemias. This is shown in the Table. I agree that this decline is probably related to the wider use of low-protein milk formulae but would suggest that the occurrence of some transient aminoacidaemias may be due to temporary immaturity of enzymes necessary in the metabolism of relevant amino-acids.

Table *Incidence of transient aminoacidaemias per 100 000 infants screened (1972–78)*

Lymphocyte response after surgery in the neonate

P. PURI, D. J. REEN, ORLA BROWNE, P. BLAKE, AND E. J. GUINEY

Our Lady's Hospital for Sick Children, Royal College of Surgeons in Ireland, and St Laurence's Hospital, Dublin

SUMMARY Fourteen neonates born with congenital malformations were investigated for lymphocyte function before and after surgery. Total leucocyte and absolute lymphocyte counts were unaltered after surgery. The mean percentage of T-lymphocytes observed either pre- or postoperatively was considerably lower than that reported in older children and adults. While there was an increase in the percentage of B-lymphocytes after operation in the infants, the absolute number of B-cells remained unchanged. The preoperative transformation response of lymphocytes to PHA (mean $12 \cdot 9 \pm 5 \cdot 4 \times 10^3$ counts/min) was little different from the postoperative values (mean $12 \cdot 4 \pm 4 \cdot 4 \times 10^3$ counts/min). These results suggest that the neonate is immunologically different from older children and adults in its response to anaesthesia and surgery.

It is now widely accepted that anaesthesia and surgical trauma in children and adults results in immunosuppression (Donovan and Soothill, 1973; Cullen and van Belle, 1975). This immunosuppressive effect is apparent within 10–15 min of induction of anaesthesia (Espanol *et al.*, 1974) , is greatest in the immediate postoperative period (Park *et al.*, 1971; Slade *et al.*, 1975), and persists for 7 to 10 days (Jubert *et al.*, 1973). There is evidence that anaesthetic drugs depress both specific and nonspecific defences against infection and that this depression influences postoperative morbidity (Moudgil and Wade, 1976).

The lymphatic tissue of the neonate is mature for both cell-mediated and humoral immune response (Miller, 1977). The capacity to mount cellular and humoral immune reactions develops at between 9 and 15 weeks of gestation, but antigenic stimulation is necessary for antibody production on a large scale (Prindull, 1974). The immune system in the newborn in response to a sudden change of environment after birth has not been extensively studied and there are no data on the effect of anaesthesia and surgery on the immune response of the neonate. The purpose of this study was to determine whether an operation performed under general anaesthesia causes changes in the lymphocyte response of the neonate and, if so, to establish the quality of these changes.

Material and methods

Fourteen infants, 10 boys and 4 girls, born with congenital malformations were studied. Eleven were born at term, two at 38 weeks' gestation, and one at 36 weeks. Pregnancy was complicated by hydramnios in 3 cases. Delivery was normal in 12 babies, breech in one, and forceps-assisted in one. Average birthweight was 3·2 kg, with a range of 2·5 to 4·7. The various congenital anomalies in the 14 neonates were neural tube defects in 7, oesophageal atresias with tracheo-oesophageal fistulas in 3, small bowel atresias in 2, and anorectal anomalies in 2.

Samples of venous blood for various immunological parameters were obtained 2 hours before surgery, usually at the time when the blood sample for crossmatch was being taken, and again 18 hours after the operation. The average age of the infant at the time of the preoperative blood sample was 1·8 days.

The patients were premedicated with atropine 0·02 mg/kg 30 min before operation. Anaesthesia was induced with oxygen, nitrous oxide and 2% halothane, and relaxed for intubation with succinylcholine, 1 mg/kg. For the maintenance of anaesthesia, 50% nitrous oxide in oxygen and, if necessary, 2% halothane were used. Pancuronium bromide (Pavulon) 0·1 mg/kg was used for further

relaxation in patients undergoing surgery for intestinal obstructions and oesophageal atresias.

The average operating time including anaesthesia was 95 min, with a range of 50 min to 3½ hours. Only one of the 14 infants required blood transfusion during surgery. Two babies were on antibiotics before blood samples were taken.

Blood samples for lymphocyte population studies and mitogen response to PHA were collected in sterile tubes containing preservative-free heparin (20 IU/ml). Blood for total leucocyte and absolute lymphocyte counts was collected in sodium EDTA blood tubes.

Total leucocyte and absolute lymphocyte counts. The leucocyte count was made on an electronic cell counter (Coulter Counter Model ZF), and the differential white cell counts were made on blood smears using Giesma stain. 200 leucocytes were counted to determine absolute cell numbers.

Separation of mononuclear cells. 2 ml heparinised blood was allowed to sediment at room temperature for an hour. The leucocyte-rich supernatant was layered on to a Ficoll-Hypaque gradient of density 1·077 (24 vol 9% Ficoll and 10 vol 33·9% Hypaque) and lymphocytes were separated after centrifugation at 800 *g* for 10 min. The lymphocytes were washed twice in medium 199 and adjusted to a concentration of 10^6 cells/ml in the same medium. This cell suspension was used for T-cell, B-cell, and null cell counts.

Spontaneous erythrocyte rosettes. 0·25 ml of cell suspension was mixed with an equal volume of a 0·5% suspension of washed sheep red blood cells (SRBC) and incubated at 37°C for 15 min. The cell preparations were then centrifuged at 200 *g* for 5 min at room temperature followed by incubation at 4°C for 18 hours. The cells were resuspended and counted in a Fuchs-Rosenthal haemocytometer. A minimum of 200 lymphocytes were counted and all lymphocytes binding 4 or more SRBC were accepted as positive.

B-lymphocyte identification. 0·1 ml of a working dilution of fluorescein-conjugated antiserum to whole immunoglobulin was added to an equal volume of cell suspension and incubated at 18°C for 30 min. The cells were then washed twice in medium 199, resuspended in one drop of phosphate buffered glycerol, and mounted on conventional microscope slides immediately before ultraviolet microscopical examination, using incident (epi) illumination.

PHA response. Cells collected in Ficoll-Hypaque gradient were resuspended in Dulbeccos Mod. medium (25 mmol/l Hepes buffer with L-glutamine) containing 10% fetal calf serum and 100 units penicillin and streptomycin/ml. Cultures were set up in triplicate in Steralin microplates, containing 10^5 cells in 200 ml medium and incubated for 3 days in 5% CO_2 and 95% air at 37°C.

PHA-P (Difco) was used as mitogen in doubling dilutions from 1/2 to 16×16^{-3}. After 68 hours' incubation, 0·4 μCi ^{3}H-thymidine was added to each culture and the cells were harvested on to glass fibre discs after a further 4 hours' incubation. The discs were washed twice in 10% TCA and twice in methanol, and then dried and counted in a liquid scintillation counter. A dose response curve to PHA was obtained for each infant.

Statistical method. The significance of difference between the mean preoperative and postoperative values was calculated using Student's *t* test for two independent observations.

Results

Total leucocyte and absolute lymphocyte counts. The total leucocyte count (Table 1) showed a wide variation in the numbers of leucocytes both pre- and postoperatively. Even though the mean total leucocyte count showed a drop from 17 264 cells/mm³ ($17\cdot3\times10^9$/l) preoperatively to 15 407 cells/mm³ ($15\cdot4\times10^9$/l) postoperatively, half of the patients showed an actual increase in the postoperative total leucocyte count. The preoperative absolute lymphocyte counts were not significantly different from postoperative counts (Table 1).

T- and B-lymphocytes. The percentage of B-lymphocytes increased after surgery in 9 out of 10 infants. While there was an increase in the mean percentage of B-lymphocytes after surgery, the absolute number of B-cells remained unaltered (Table 2). Both the

percentage and the absolute number of spontaneous E-rosettes (T-cells) were unaffected by anaesthesia and surgery. The percentage of null cells was noticeably high in the infants and was not appreciably changed after surgery. The mean percentage of null cells was 39·6 ± 18·6 preoperatively and 34·7 ± 13·6 postoperatively (Table 2).

Table 3 *Maximum PHA mitogen response (counts/min × 10^3) in the neonate pre- and postoperatively*

	No. tested	*Mean + 1 SD*
Preoperative	9	12·9 ± 5·4
Postoperative	9	12·4 ± 4·4 NS

NS = Not significant (P>0·05).

PHA response. The rate of ^{3}H-thymidine incorporation after PHA stimulation was greatest at a concentration of either 0·06 or 0·1 μl/ml in all infants. The transformation response of lymphocytes to PHA did not change after surgery, the preoperative mean being 12·9 ± 5·4 × 10^3 counts/min and the postoperative being 12·4 ± 4·4 × 10^3 counts/min (Table 3). There was no significant difference at any of the PHA concentrations used in the dose response curve before or after surgery (Figure). Appreciable levels of spontaneous ^{3}H-thymidine incorporation (1·2 ± 0·9 × 10^3 counts/min) were observed in all patients. At optimum PHA concentrations, a wide variation of maximum incorporation of ^{3}H-thymidine was observed, especially in patients before operation.

Discussion

While most authors have reported that anaesthesia and surgical trauma in adults and older children produces depression of the cellular immune response

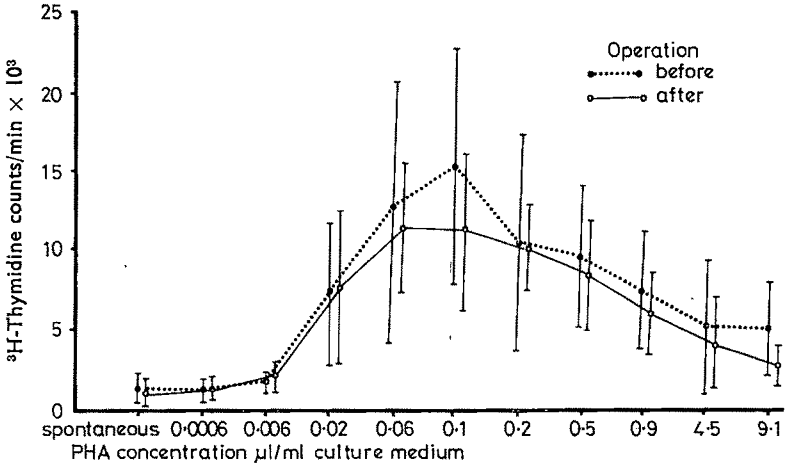

Figure *PHA response to increasing mitogen concentrations before and after surgery. Each point represents mean ± 1 SD for 9 patients.*

(Donovan and Soothill, 1973; Cullen and van Belle, 1975), we have been unable to support this finding in the neonate. No overall differences could be demonstrated between the preoperative and postoperative immune response. A number of factors must be considered in relation to this study in the neonate which may explain the differences in our results from those previously reported, and also may help to explain the clearly divergent reported observations on the effect of surgery on the immune response in adults.

When making comparisons of results in relation to the immune status of patients it is essential to select and control as closely as possible a homogeneous group of subjects and to eliminate wide variations in relation to age, degree of immunological sensitisation, clinical status, as well as factors that are known directly to affect immunological competence—such as therapeutic regimens, blood transfusion, and infection.

Age of the patient is of prime importance in relation to immune status, as T-lymphocyte subpopulations and mitogen responsiveness are diminished with increasing age (Augener *et al.*, 1974; Pisciotta *et al.*, 1967). Some patients in our study were relatively homogeneous in regard to age, with a mean age of 1·8 days and a range of 1 to 3.

All patients had a similar brief exposure to their antigenic environment since they were all directly transferred soon after birth from the maternity hospital to the referral centre for urgent surgery.

Several investigators have reported that immunosuppression after surgery is related primarily to the extent of tissue trauma, a more profound decrease in lymphocyte responses occurring after major rather than minor operations (Berenbaum *et al.*, 1973; Salo, 1978). The present study shows that major surgery in the neonate for congenital anomalies is not associated with depression in the immune responsiveness.

Total leucocyte and absolute lymphocyte counts were not significantly altered after surgery. This may be explained by the observations that the infant is undergoing active bone marrow generation with rapid alteration in peripheral blood leucocyte counts, coupled with a developing lymphocytosis relative to later life (Andersen and Andersen, 1974). This normally occurring lymphocytosis in the first few days of life may counteract any specific leucopenic effect of surgery in the neonate.

Similar conditions may explain the unaltered absolute numbers of T- and B-lymphocytes postoperatively. Even though 9 out of 10 infants showed an increase in the percentage of B-lymphocytes after surgery, this increase was not apparent in the absolute numbers owing to the wide range of total leucocyte counts present in the newborn. The mean percentage of T-cells observed in this study either pre- or postoperatively was considerably lower than that reported for older children and adults (Fleisher *et al.*, 1975). Similarly the percentage and actual numbers of null cells in the infant were higher when compared with the reported levels in adults.

These observations are further supported by our findings on mitogen response to PHA after anaesthesia and surgery. No significant change was found in the transformation response of lymphocytes to PHA after operation. However, an appreciable level of spontaneous ^{3}H-thymidine incorporation was observed in all patients ($1 \cdot 2 \pm 0 \cdot 9 \times 10^3$ counts/min). This may further reflect an active development of lymphocyte production and maturation taking place in the neonate.

These finding suggest that the neonate is immunologically different from older children and adults in its response to known immunosuppressive factors, such as anaesthesia and surgery. Further studies are required on factors that affect the immunological capacity of the neonate in order to understand more fully the complex immunological status of the developing infant in the first few days of life.

Critical assessment of small bowel biopsy in children

J. F. T. GLASGOW, C. W. B. CORKEY, AND A. MOLLA

The Department of Child Health, The Queen's University of Belfast

SUMMARY 176 biopsies of small bowel mucosa taken during a 5-year period from 162 children were reviewed, and 92 of them were subjected to quantitative measurement using surface/volume ratio and intraepithelial lymphocyte counting. There was good general agreement between stereomicroscopical appearance of fresh tissue, routine pathology reporting, and our independent histological assessment. Most of those in which there was divergence of opinion (11–15%) had intermediate mucosal changes. There was a significant difference between the surface/volume ratio for each of the three grades of histology ($P<0\cdot001$, $<0\cdot001$, $<0\cdot01$), indicating a relationship between qualitative and quantitative methods of assessment. The range of measurements in intermediate biopsies overlapped those of the other two grades. In the 92 biopsies there was a correlation between surface/volume ratio and intraepithelial lymphocyte count ($r = -0\cdot56$; $P<0\cdot001$) which may reflect our clinical experience, in that 88% of the biopsies were graded as either normal or flat (probable coeliac disease). Very short children had shorter villi than those with nonspecific diarrhoea and a more normal height.

Small bowel biopsy is the key investigation for the diagnosis of enteropathies, such as coeliac disease, and it is imperative that a proper interpretation of the intestinal histology is made. This is usually assessed subjectively and may be made more difficult by poor orientation of the mucosa before histological sectioning. In reviewing our experience we collated the histological material from all children biopsied between January 1972 and December 1977 inclusive. More than half of the specimens had also been subjected to morphological assessment using the techniques of surface/volume ratio measurement (Dunnill and Whitehead, 1972) and intraepithelial lymphocyte counting (Ferguson and Murray, 1971).

Methods

Patients. 162 patients (aged 3 months to 14·5 years) had biopsies of the small bowel mucosa because of clinical or laboratory features suggesting small gut enteropathy. A diagnosis of coeliac disease was made in 49 children. 11 others had possible postinfectious diarrhoea, 4 dermatitis herpetiformis, 4 giardiasis, 3 cystic fibrosis without associated bowel pathology, 2 an immunological disorder, 2 short bowel syndrome, and one each with isolated growth hormone deficiency, severe iron deficiency anaemia, and diabetes mellitus with pronounced hepatomegaly (Mauriac's syndrome). The biopsy was normal in 84 children.

Qualitative assessment. Peroral jejunal biopsies were taken under fluoroscopic control, at the ligament of Treitz with a Crosby-Kugler, one-hole, paediatric capsule. The specimen was placed on black filter paper, covered with normal saline, its mucosal surface immediately examined with a Wild stereomicroscope, the majority by one observer (J.F.T.G.), and graded as normal, intermediate, or flat according to the classification of Shmerling (1970). The tissue was then fixed in 10% formalin and processed for routine histological reporting by a pathologist. The same slides were graded independently (J.F.T.G.) as normal, intermediate, or flat before the pathology report was known. It is these two forms of histology which are referred to subsequently, but it is with the independent grading that quantitative measurements are compared.

Quantitative measurements. These were made without reference to the above findings in 92 biopsies.

Surface/volume ratio (SVR)

This was measured (Dunhill and Whitehead, 1972) by viewing the histological specimen through a

graticule inserted in the microscope eyepiece. Inscribed on the graticule were (15 lines of equal length connecting the vertices of a regular hexagonal point network (Weibel, 1963). SVR is given by the formula c:lh, where c is the total number of times a line *cuts* the epithelial surface, h the total number of times the end points of a line *hit* the mucosa between muscularis mucosae and epithelium. At least 200 hits were made. The mucosal volume (MV) is the mean number of hits h, for each position of the graticule in relation to the mucosa. The length of the line, l, projected on the histology was 1·4 mm. Magnification was kept constant throughout.

Counts of intraepithelial lymphocyte (IEL)
These were made according to Ferguson and Murray (1971). Differential counts of cell nuclei were carried out within the epithelium where the plane of section passed vertically through basement membrane and enterocytes. Their nuclei and those of lymphocytes could thus readily be distinguished; goblet cells were ignored. In histologically normal and intermediate specimens, counts were made on the sides and tips of the villi and in flat biopsies surface cells were counted. In most biopsies at least 400 epithelial cells were counted. In a few flat biopsies however, which were small in size with distortion of the epithelial cells, only 200 could be accurately counted. The results were expressed as IEL per 100 epithelial cells.

Normal ranges were derived by plotting cumulative percentages on probability graph paper (Hoffmann, 1963). Statistical comparisons were made using the SPSS system (Nie *et al.*, 1975) and Student's *t* test.

Results

Qualitative assessment. By comparison with our independent grading, stereomicroscopical examination graded the majority of normal and flat biopsies correctly (Table 1). This was not so for intermediate changes, as there was a tendency for stereomicroscopy to suggest a degree of abnormality less severe than could be confirmed histologically by us.

Table 1 *Independent histological grade compared with stereomicroscopic grade*

Independent grade	*Stereomicroscopic grade*				
	Normal	*Intermediate*	*Flat*	*NE*	*Total*
Normal	95	8	—	5	108
Intermediate	8	11	2	—	21
Flat	—	8	37	2	47

NE = Not examined.

Table 2 *Independent histological grade compared with pathology report*

Independent grade	*Pathology report*			
	Normal	*Intermediate*	*Flat*	*Total*
Normal	93	12*	—	105
Intermediate	—	19	—	19
Flat	—	4*	44	48

*See Table 5.

Comparison of the pathology report with our independent grade tended also to be in general agreement (Table 2). Of the 35 biopsies reported as intermediate however, independent grading was in agreement in 19 and, of the remaining 16, 12 were normal and 4 flat; these 16 are discussed below.

Quantitative measurements. The SVR between each of our three independent grades showed highly significant differences (Tables 3 and 4). There was no overlap between the range in normal and flat mucosae, but the SVR of the intermediate grade overlapped each of the others to a considerable degree. Significant differences were also present in MV between normal and flat biopsies. There was no difference between the intermediate and either of the other two grades. Each of the ranges for MV greatly overlapped.

The normal range for lymphocytes per 100 epithelial cells (probability graph plot) was 3–37. IEL counts were significantly different when flat biopsies were compared with other grades. The range in all however, overlapped considerably. There was a significant correlation between the IEL count and SVR ($r = -0·56$; $P<0·001$), although this was not the case within the normal or flat grades ($r = -0·03$).

Table 2 shows 19 biopsies about which the pathology report and independent grading were in agreement. There was a difference of opinion about the other 16 specimens (already mentioned). These were coded and submitted to 'blind' quantitative analysis. Data for SVR, MV, and IEL were within the ranges quoted in Table 3, but only SVR and MV provided clear separation between normal and flat grades (Table 5).

We studied 13 biopsies in which the muscosa was graded as either normal or intermediate. These were taken from 10 children with coeliac disease who were taking a gluten-free diet or undergoing gluten challenge (Figure). In 11 the SVR and MV divided those with qualitatively normal mucosa from those with intermediate changes; 2 were not assessed for technical reasons. None with a SVR below a value of 40 or MV above 11 had normal morphology. Gluten challenge tended to reduce the SVR and

increase the MV, while a gluten-free diet reversed these trends. One child who was being gluten challenged had a normal mucosa, but this had been in progress for only one week. One other had intermediate changes although a normal IEL count, which may have been because the biopsy was from the second part of the duodenum. The IEL counts did not always correspond to morphological grading. High counts were noted in 4 children with intermediate changes who were taking a normal diet. Two other patients had normal IEL counts, but in each, challenge with gluten powder, 5 g daily, had begun only one week before; when biopsied again having been on a normal diet for some months each had abnormally high counts (Figure).

Four patients with giardiasis, all of whom had normal mucosae, had widely differing IEL counts; 3 were within the normal range, but one child with hypogammaglobulinaemia and a heavy infestation had a count of 58. Three children with dermatitis herpetiformis and normal mucosae had normal IEL counts (18, 22, 25) and one, graded as flat, a count of 55.

Finally, quantitative data in children presenting with short stature (height <3rd centile) in whom no intestinal lesion was found, had a significantly smaller mean SVR than those whose complaint was of non-specific diarrhoea (Table 6). The MV and IEL counts in the two groups however, were virtually identical.

Discussion

Jejunal biopsy, now accepted as the key investigation in the diagnosis of small bowel enteropathy, has shown that the range of possible changes in

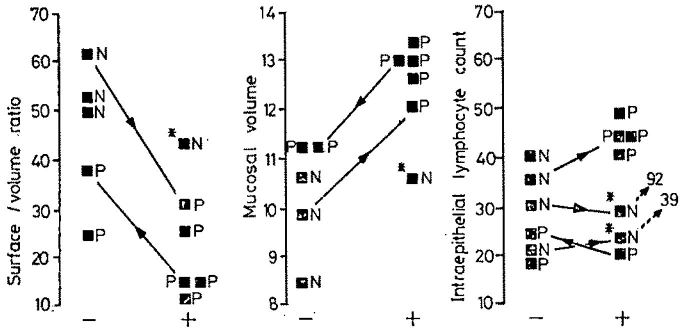

Figure *Quantitative measurements in children with coeliac disease in whom biopsies were not flat because the children were on a gluten-free diet (—) or being gluten challenged (+); N, normal mucosa; P, intermediate changes. Arrows indicate serial biopsies in 4 children. Asterisk indicates data on two patients on gluten challenge for one week only.*

various disorders is very wide. As these changes are usually described in purely subjective terms it is not surprising that interobserver variation occurs (15% in this study) or that this is more likely in the intermediate part of the range, rather than at either extreme (Table 2). Similar variation was experienced when stereomicroscopical examination of fresh tissue was compared with our independent histological grading (Table 1). Although these two methods of examination are not strictly comparable, differences (11%) again tended to be in the intermediate group. Others have reported similar findings (Rubin and Dobbins, 1965; Anderson, 1966). Two further problems which lead to interpretational difficulty are variations in villous architecture found between duodenal and jejunal mucosa (Anderson, 1966), and perhaps more important, technical problems in orientating the specimen before histological sectioning (Brandborg *et al.*, 1959). This is more likely if the biopsy is very small as may be the case if a paediatric instrument is used.

One attempts to combat such inherent variability by taking specimens from a constant site in the gut (Rubin and Dobbins, 1965), striving for perfection in preparing the mucosa so that villi are sectioned vertically, rather than tangentially, and by examining them oneself. It is also helpful to carry out quantitative assessment on biopsies where histological reports are equivocal (Table 5) and, although not the case throughout much of the current study, it should be helpful to have the same pathologist report on all biopsies. Standardisation and comparability are more important with the increasing use of serial biopsies in children with suspected coeliac disease.

Various quantitative assessment methods have been used in the past. Risdon and Keeling (1974) pointed out, that to be of value an assessment must be accurate, reproducible, and have well-defined normal ranges. More arbitrary methods—such as the measurement of villus length and width—fail to satisfy these criteria (Madanagopalan *et al.*, 1965). The methods used here have been validated (Ferguson and Murray, 1971; Risdon and Keeling, 1974) and the normal ranges seem reproducible, although they will not overcome difficulties imposed by specimen distortion or poor histological preparation. Counting of IEL might more accurately be done per unit length of mucosa (Skinner and Whitehead, 1976), but provided the original method is followed, intercentre variation should be negligible.

A highly significant difference in SVR was found between the three histological grades, thus indicating a close relationship between quantitative and qualititative assessments. The fact that the range for normal mucosa overlapped that for intermediate changes accords with the findings of Risdon and Keeling (1974) and tends to reduce the clinical value of SVR in distinguishing biopsies with mild changes from normal (Table 3). On the other hand, when used to assess serial biopsies from the same individual SVR may be more helpful (Figure).

We confirmed that flat mucosa had a volume significantly greater than normal, which is related to crypt hyperplasia, mucosal swelling, and oedema (Whitehead, 1971). The actual values recorded for MV in each of the three grades were uniformly lower than those of others (Dunnill and Whitehead, 1972; Risdon and Keeling, 1974). Since MV is an absolute measurement ($\bar{h}$), as opposed to a ratio, one might expect a greater intercentre variation than with SVR. These differences could be related to such things as different degrees of handling mucosae after biopsy, or to technical factors—for example varying degrees of tissue shrinkage during preparation. Because of these factors and the fact that ranges of the three grades of mucosa overlap, MV is considered less useful than SVR, particularly in comparing data between different centres, unless identical methods are strictly followed.

Unlike data for SVR and MV in normal biopsies, those for IEL counting showed a distribution which was mildly skewed towards the upper end. This was probably because we had as our group of normal biopsies, tissue which, although architecturally normal, was taken from children, some of whom had bowel symptoms or growth failure, rather than from truly normal individuals, such as the normal siblings of coeliac patients (McNicholl *et al.*, 1976; Mavromichalis *et al.*, 1976). None the less, by using the probability plot as a means of eliminating values at the extremes of the range which are less likely to be completely normal, in spite of their villous architecture, we derived a normal range (and mean) similar to those quoted (Ferguson, 1977).

We have found a significant relationship between morphological alteration in the mucosa and lymphocytic infiltration of the epithelial layer. This in no way implies a causal link between the two and in clinical practice a number of our cases demonstrated that the two modalities of abnormality behaved in an independent manner. A child of 20 months with a fatal defect of cell-mediated immunity, who had intermediate changes, with SVR of 5·7, had an IEL count of only 9. Several of our flat biopsies characteristic of coeliac disease have also had low IEL counts, which may reflect conscious or unconscious withdrawal of gluten from the diet in children old enough to select their own food. On the other hand, 3 young children had morphologically normal biopsies but abnormally high IEL counts. The most striking was a child with immunodeficiency and heavy giardiasis whose IEL count was 58. The other two children with diarrhoea and failure to thrive also had counts >40 and were clinically similar to the infants reported by Ferguson *et al.* (1976). It was thought their high IEL counts may have been an indication of food allergy. Whether this was the case in our patients we cannot be certain, however, it may be significant that in the group of children presenting with nonspecific diarrhoea, the IEL counts were similar to those with short stature *per se* (Table 6). None the less, a correlation has been shown between SVR and IEL counts and it seems likely that this is because 88% of our biopsies proved to be either flat, the majority with high counts consistent with coeliac disease, or normal, most having normal IEL counts. Others who have a quite different practice, with many more biopsies of intermediate grade have recently reported no relationship between surface area (c), one of the two variables in the SVR, and the IEL count (de Peyer *et al.*, 1978).

One area where quantitative methods of assessment may prove to be particularly useful is in following serial biopsies from the same patient. So far we have had only a limited experience of this. McNicholl *et al.* (1976) studied 36 children, using IEL counting, over a number of years and feel that quantitative assessment is better than subjective methods of interpretation.

Very short normal children, the majority with genetic short stature, had villi with significantly smaller surface areas than those presenting with nonspecific diarrhoea (Table 6) and it would seem likely that this is because their villi are actually shorter. This seems a possible explanation since the mucosal volumes, the one other variable, was not significantly different in the two groups. Indeed it seems reasonable that very short children may have proportionately shorter villi.

The time required to carry out these counting techniques is brief. The SVR and MV can with practice be done in 2–3 minutes and the IEL count in a comparable time.

We thank Professor Brian McNicholl and Dr Helen Mawhinney for reviewing this paper.

Use of growth hormone-gel

BARBARA LIPPE, S. DOUGLAS FRASIER, AND SOLOMON A. KAPLAN

Department of Pediatrics, UCLA School of Medicine, and Department of Pediatrics, University of Southern California, School of Medicine, Los Angeles

SUMMARY We evaluated the efficacy of a depot preparation of growth hormone (GH) in a 15% gelatin solution (GH-gel) in the treatment of 15 growth hormone-deficient children. The studies were designed to see if prolonging absorption of GH to achieve lower more physiological concentrations of GH in plasma would decrease the frequency of injection, reduce the amount of GH needed for effective therapeutic response, and improve the response to long-term treatment. We found that after a single dose of GH-gel the plasma concentrations of GH were lower than those achieved after the standard aqueous preparation. The preparation was efficacious in promoting growth and our 1st study of 6 patients suggested that GH-gel given twice a week had a growth response equal to that of the three-times a week aqueous schedule. However both schedules resulted in the frequently observed decreased growth rate during the second treatment year. Our 2nd study, attempting to ameliorate this waning effect by using the GH-gel preparation twice a week in a weight-adjusted dose during the entire second year did not resolve the problem. Thus, GH in depot gel results in more physiological plasma concentrations of GH and may be beneficial in reducing the quantity of hormone needed and the injection frequency but it does not offer a solution to the waning response to the long-term administration of GH.

The administration of growth hormone (GH) extracted from pituitaries has provided successful treatment for children with growth hormone deficiency. However, the optimal dose and administration schedule has yet to be established (Preece *et al.*, 1976; Frasier *et al.*, 1977). The quantity of GH given to each child is limited by its availability and cost, and the need to give the preparation repeatedly by the intramuscular (IM) route.

The usual method of administration results in an unphysiological pattern of the concentration of GH in plasma. After a single IM injection of GH in aqueous solution, peak concentrations are reached in 2–4 hours. The peak levels of GH are in the range usually found in patients with acromegaly. After this very high peak there is a rapid decline in the concentration of GH and the hormone disappears from plasma within 12–24 hours (Frasier *et al.*, 1969).

We thought that a depot preparation of GH might prolong absorption from the site of injection and maintain lower but more physiological plasma concentrations for longer periods of time, thus decreasing the amount of GH needed to maintain an effective therapeutic response, and improving the therapeutic response to long-term GH administration. Our experience with GH in a 15% gelatin solution (GH-gel) in the treatment of 15 patients with growth hormone deficiency is reported.

Materials and methods

Patient population. Patients with growth hormone deficiency diagnosed by testing as previously described (Lippe *et al.*, 1971) and followed up at the UCLA Pediatric Endocrine Clinic were studied under an approved National Pituitary Agency (NPA) protocol. The patients ranged in age from 7–15 years, were all prepubertal at the time of starting GH treatment, and were all growing at a rate of 3 cm or less in the year before treatment.

Preparation of GH for injection. Aqueous growth hormone was prepared by adding sterile, distilled water to GH as provided by the NPA. Gelatin (gel) USP was prepared as a 15% weight/volume solution

in freshly distilled water and packed in 10 ml rubber-stoppered vials without preservative. The vials of gelatin were sterilised by autoclaving. To prepare GH for injection, the gelatin vial was warmed to liquidity under warm, running water by the patients' parents and used as diluent for the NPA GH in the same way that sterile water was used. Once mixed, each GH-gel vial provided material for 4–6 injections. The material was refrigerated between injections and rewarmed to liquidity before administration of each dose.

Laboratory methods. The concentration of GH in plasma was measured by a double antibody radioimmunoassay (Boden and Soldner, 1967). Binding antibodies to GH were measured as previously described (Frasier *et al.*, 1974).

GH blood levels. The concentrations of GH achieved in plasma, after a single IM injection of either 2 international units (IU) GH in aqueous solution (GH-AQ) or 2 IU GH-gel, were measured in 6 patients. All patients had an indwelling scalp vein needle with a heparin lock placed in a hand vein and blood was sampled at 0, 1, 2, 4, 6, 8, 12, 18, 24, and 30 hours after the injection. In those patients receiving GH-gel, sampling continued at 36, 42, 54, 60, and 72 hours. Plasma was separated and stored at −20°C until assay.

Treatment protocols.

Study 1

Six patients entered an initial 30-month crossover study to test the efficacy of the gel preparation and to examine the therapeutic response to a lower dose of hormone in the depot form. Cases 1–3 were started on 2 IU of GH three-times a week (6 IU/week) in aqueous solution (GH-AQ) for 6 months followed by 2 IU twice a week (4 IU/week) in gel for 6 months. After a 6-month period during which no GH was administered, these patients resumed treatment with 6 months of GH-gel (2 IU twice a week) followed by 6 months of GH-AQ (2 IU three-times a week). Cases 4–6 followed a reverse schedule. They received GH-gel for 6 months followed by GH-AQ for 6 months. After a 6-month period of the treatment they received GH-AQ followed by GH-gel.

Study 2

After the crossover study had been completed, a second group of 9 patients (Cases 7–15) began a 30-month regimen of GH therapy with doses adjusted for weight. Therapy was begun with GH-AQ in a dose of 0·1 IU/kg per injection, administered three-times a week (0·3 IU/kg per week). After one year of this schedule and a 6-month period of no treatment, GH-gel was administered at a dose of 0·15 IU/kg twice a week. Thus, patients received the same weekly dose as during the first year (0·3 IU/kg per week) in two injections. The dose of GH-gel was again adjusted to body weight at the beginning of the second year.

Results

GH blood levels. The mean plasma concentrations of GH reached after single injections of GH-AQ and GH-gel are shown in Table 1. The GH-AQ preparation resulted in a rapid increase in GH by one hour, a wide peak of 128·4 ± 77·5 mU/l at 2 hours, and concentrations in excess of those obtained after the gel preparation until 8 hours after the injection. By contrast, there was no clear peak after the gel preparation, and the concentrations achieved in the first 8 hours were much lower than with the aqueous, with maximum concentrations of only 37·9 ± 8·8 mU/l. By between 12 and 18 hours the gel preparation had maintained levels in excess of the aqueous preparation and by 24 hours both resulted in virtually undetectable concentrations. When we looked at the peak concentrations of GH achieved by each patient, irrespective of time, the patients receiving GH-AQ had a peak of 158·6 ± 62·2 mU/l (SEM) with a range of 95·7–283·1 mU/l, while the mean peak of those receiving GH-gel was 46·6 ± 11·9 mU/l and the range 26·7–68·0 mU/l.

While the number of patients in each group is small and the variability great (precluding meaningful statistical analysis), there are clear differences in the pattern and concentrations of GH achieved in blood after the two modes of administration. The levels and

pattern after GH-AQ are similar to those which we previously reported (Frasier *et al.*, 1969). In contrast, the administration of GH-gel leads to a slower increase in blood levels, a lower and more prolonged peak in growth hormone concentration, and persistence of detectable growth hormone for a longer time.

Study 1

Table 2 shows the growth rates for Cases 1–6 while they received alternate courses of GH-AQ and GH-gel. The results of the first year of this study were confounded by the development of hypothyroidism in 3 patients (Lippe *et al.*, 1975). However, when the 6-month periods during which patients with untreated hypothyroidism are eliminated from consideration, it is clear that in the first year of treatment there was no overall difference in the rate of growth during the administration of GH-AQ (3·9 ± 0·2 cm/6 months) and during the administration of GH-gel (3·9 ± 0·3 cm/6 months). The small numbers preclude meaningful statistical comparison of the effects of the sequence in which each GH preparation was given.

In the second year of treatment there was also no difference in the rate of growth during the administration of GH-AQ (3·2 ± 0·2 cm/6 months) and the administration of GH-gel (3·1 ± 0·2 cm/6 months). The sequence in which the two GH preparations were given did not significantly alter the overall response. Patients who received GH-AQ first grew 6·2 ± 0·1 cm/year and patients who received GH-gel first grew 6·4 ± 0·2 cm/year.

However, there was a decrease in the rate of growth during the second year of GH administration. The growth rate for all treatment periods in which hypothyroidism was not a variable ($n = 9$) during the first year was 3·9 ± 0·2 cm/6 months. During the second year of treatment the growth rate for all treatment periods ($n = 12$) decreased to 3·1 ± 0·2 cm/6 months ($P<0{\cdot}01$).

Table 2 *Growth rate (cm/6 months) while receiving alternate courses of GH-AQ and GH-gel*

Case	*First year*		*Second year*

*Hypothyroidism developed during these 6-month intervals.

Study 2

Table 3 shows the growth rates of Cases 7–15 during the year they received GH-AQ (0·1 IU/kg three-times a week) and during the year they received GH-gel (0·15 IU/kg twice a week). Growth rates for the 6-month 'off' period between the two treatment years have been extrapolated to a 12-month period and are shown for comparison. As hypothyroidism had been a problem in the 1st study, these patients were frequently monitored and in the one patient in whom the T4 decreased precipitously (Case 7) supplementary thyroxine was instituted within weeks.

The growth rate of 8·5 ± 0·4 cm/year during the first year of GH-AQ compares favourably with the therapeutic responses seen in other studies. In the second year with the weight-adjusted GH-gel preparation, there was a significant decrease ($P<0{\cdot}001$) in rate to 5·6 ± 0·4 cm/year.

Sera obtained from 7 patients after 6–12 months of GH-gel were tested for binding antibody to GH. Significant antibody was present in two samples.

Discussion

The most commonly used treatment regimens for the administration of GH to hypopituitary children are based on empiric observations of successful therapy (Raben, 1958; Escamilla *et al.*, 1961). Actual dose schedules, however, vary between countries and investigative protocols. Some schedules use doses which vary with body size or weight (Ferrandez *et al.*, 1970; Hall and Olin, 1972; Kirkland *et al.*, 1973; Frasier *et al.*, 1977), while others do not (Tanner *et al.*, 1971; Aceto *et al.*, 1974; Preece *et al.*, 1976). The variables of patient heterogeneity, additional hormonal requirements, and age at start of treatment have made the analysis of results difficult and have all contributed to less than ideal recommendations for the initial dose of GH. Administration of aqueous preparations results in radioimmunoassayable concentrations of GH which quickly reach very high

Table 3 *Growth rate (cm/year) while receiving GH-AQ followed by GH-gel*

	Cases									*Mean± SEM*
	7	*8*	*9*	*10*	*11*	*12*	*13*	*14*	*15*

levels and then fall rapidly. Long periods ensue before the next injection during which GH is undetectable (Frasier *et al.*, 1969). Thus, the present methods of administration result in abnormal patterns of plasma hormone levels characterised by peak concentrations, similar to those seen in acromegaly.

The current study was undertaken to test the efficacy of a depot GH-gelatin preparation designed to prolong time of absorption. We hoped to achieve adequate growth with less frequent injections and to reduce the total amount of hormone administered. We also studied the effect of GH-gel in ameliorating the deceleration in growth rate experienced by most patients after the initial rapid growth of the first year of treatment.

Our results demonstrate that the IM administration of a single injection of GH in gelatin reduces the peak concentration of GH and prolongs its absorption when compared with an injection of the same amount of GH in aqueous solution. The peak concentrations achieved after the injection of GH-gel resemble those seen in association with sleep in normal children (Underwood *et al.*, 1971; Eastman and Lazarus, 1973).

Although the number of observations was limited by the development of hypothyroidism in 3 patients, our initial study appears to indicate that GH-gel (2 IU twice a week) is as effective as an aqueous solution of GH (2 IU three-times a week) during both the first and second year of treatment. Thus, the administration of GH in gelatin appears to have stimulated the same rate of growth as aqueous GH with a significant saving in the quantity of hormone. Theoretically these savings would provide treatment for one more patient for every 2 currently being treated. At the same time, the number of injections and cost of treatment would be reduced. Because the number of patients treated in our study is small, these conclusions must be considered tentative. A larger group of patients needs to be treated with GH in gelatin to test the validity of our preliminary results.

As in previous studies in which GH was given for more than one year, the response waned during the second 12 months of GH therapy (Soyka *et al.*, 1970; Kirkland *et al.*, 1973; Aceto *et al.*, 1974; Frasier *et al.*, 1977). In our 2nd study we attempted to ameliorate this waning effect by administering GH-gel in the same total weekly dose as in the earlier GH-AQ therapy, using twice-weekly rather than three-weekly injections. We were not successful. The growth rate in patients receiving GH-gel was significantly less than that observed during the previous year of therapy with GH-AQ. In view of the comparable effects of the two GH preparations during the second year of our initial study, this diminished response is most likely due to time and not to the preparation. As previous analysis (Frasier *et al.*, 1977) indicates that a three-times a week dose schedule may be preferable to twice a week, we might have been more successful if GH-gel had been given three-times a week in a dose of 0·1 IU/kg. This hypothesis remains to be tested. A solution to the problem of waning response as observed in this and other studies remains to be found.

We thank Ms Jean Hilburn for technical assistance, Ms Sandra Dills for help with this manuscript, and Dr S. Raiti and the National Pituitary Agency for supplying the human growth hormone for this study. The study was supported in part by a grant from the USPHS, RR865.

Pulmonary hypoplasia: lung weight and radial alveolar count as criteria of diagnosis

S. S. ASKENAZI AND M. PERLMAN

Hadassah Hospital, Jerusalem

SUMMARY A working definition of pulmonary hypoplasia (PH) was established by retrospective assessment of lung growth both in recognised and hypothetical PH-associated conditions. Lung weight: body weight ratios (LW:BW) were calculated, and morphometry was determined by the radial alveolar count (RAC) (Emery and Mithal, 1960). Both parameters were reduced compared with those of normal controls in diaphragmatic hernia, anencephalus, anuric renal anomalies, chondrodystrophies, and osteogenesis inperfecta. Comparison of LW:BW ratio and RAC indicated that the RAC was the more reliable criterion of PH, LW:BW ratio of ≤0·012 (67% of mean normal ratio) and/or RAC of ≤4·1 (75% of mean normal count) are suggested as diagnostic criteria of PH. Evidence of PH was incidentally discovered in a number of clinically unsuspected cases and retrospectively clarified the clinical and radiological findings. Routine assessment of lung growth should be an essential part of the neonatal necropsy.

Pulmonary hypoplasia (PH) is a poorly defined condition considered to be almost invariably secondary to other anomalies and is usually diagnosed in association with them; primary or isolated PH has not been reported (Reale and Esterly, 1973). PH is lethal within hours of birth in many instances of diaphragmatic hernia (Potter, 1961; Kitagawa *et al.*, 1971; Reale and Esterly, 1973), anencephalus (Potter, 1961; Naeye and Blanc, 1971; Reale and Esterly, 1973), anuric renal anomalies with oligohydramnios (Potter, 1972; Reale and Esterly, 1973; Perlman and Levin, 1974; Thomas and Smith, 1974), and skeletal anomalies restricting thoracic volume (Finegold *et al.*, 1971). There is however a spectrum of severity of PH, often proportional to the severity of the underlying condition, and sublethal forms exist (Kohler and Babbitt, 1970; Chatrath *et al.*, 1971; Perlman *et al.*, 1975).

Because histological findings lack specificity (Potter, 1961; Reale and Esterly, 1973), diagnosis depends on detection of low lung weight in relation to body weight (low LW:BW ratio), or of low alveolar counts determined by morphometric methods (Reale and Esterly, 1973). Severe PH is easy to diagnose at necropsy from the low LW:BW ratio alone, but lesser or borderline PH is more difficult to establish. There has been only one study of both LW:BW ratio and morphometry in a substantial number of pathological cases (Reale and Esterly, 1973).

These diagnostic criteria of lung growth were studied in an attempt to establish a working definition of PH. Lungs of patients dying perinatally with PH-associated conditions were examined. In addition to these anomalies, neonates with other conditions in whom there were theoretical grounds to anticipate PH were examined.

Materials and methods

Material was obtained from the pathology departments of the Hadassah University Hospital, Jerusalem; Kaplan Hospital, Rehovot; and the Soroka Medical Centre, Beer-Sheva. About 200 liveborn and stillborn subjects were selected according to recognised PH associations (diaphragmatic hernia, anencephalus, anuric renal anomalies, chronic amniotic fluid leakage, and chondrodystrophies) and, in unprecedented cases, where PH was anticipated on theoretical grounds (osteogenesis imperfecta, hydrops fetalis). In addition, PH was identified incidentally in some patients who died during the study period because of a low LW:BW ratio at necropsy (central nervous system anomalies, gross ascites due to long-standing meconium peritonitis). No patient with PH lived for more than 72 hours.

Neonatal Unit, Department of Paediatrics, Hadassah Hospital, Jerusalem
S. S. ASKENAZI, intern
M. PERLMAN, senior lecturer

'Normal' control liveborn and stillborn infants were selected randomly, but subjects with birthweights outside the 10th to 90th centile for gestational age were excluded. Patients with clinically diagnosed and pathological confirmed lung disease—such as hyaline membrane disease and meconium pneumonitis—or with congenital anomalies including heart defects other than those with PH associations were also excluded. In all control infants death resulted from either perinatal asphyxia or traumatic intracranial haemorrhage within 3 days of birth.

The following information was obtained from the necropsy record: sex, gestational age, body weight, lung weight, age at death, anatomic diagnoses, and cause of death. LW:BW ratios were computed.

Morphometry was performed by one of us (S.A.A.) at microscopical magnification of × 40, using a modification of the method of Emery and Mithal (1960), without knowledge of the anatomical diagnoses or cause of death. Before beginning the study, experience of interobserver error was obtained with the help of Professor E. Rosenmann: the error was <± 10%. A line was dropped from the centre of each respiratory bronchiole (bronchioles only partially lined with epithelium) to the nearest connective tissue septum at right-angles to the epithelium. The number of alveolar septi (as distinct from the number of alveoli counted by Emery and Mithal) cut by this line were counted. At least 10 counts were made for each patient, mainly from 2–3 histological sections.

Mean values of LW:BW ratios and of RACs and SDs of the mean were calculated for each diagnostic group. The significance of the difference of the means of each of the pathological groups compared with the control group was determined by Student's *t* test. Subgroups of infants <36 weeks' gestation and >35 weeks' gestation were treated statistically in the same manner and compared.

Results

Of about 200 cases screened for study, 111 had adequate perinatal data and histological preparations suitable for morphometry. LW:BW ratios were not available in 12 cases. Mean gestational age and mean birthweight were similar in each group. The data for LW:BW ratio and RAC for infants of gestational ages <36 weeks were compared with data for >36 weeks and there was no significant difference, so the total data were analysed.

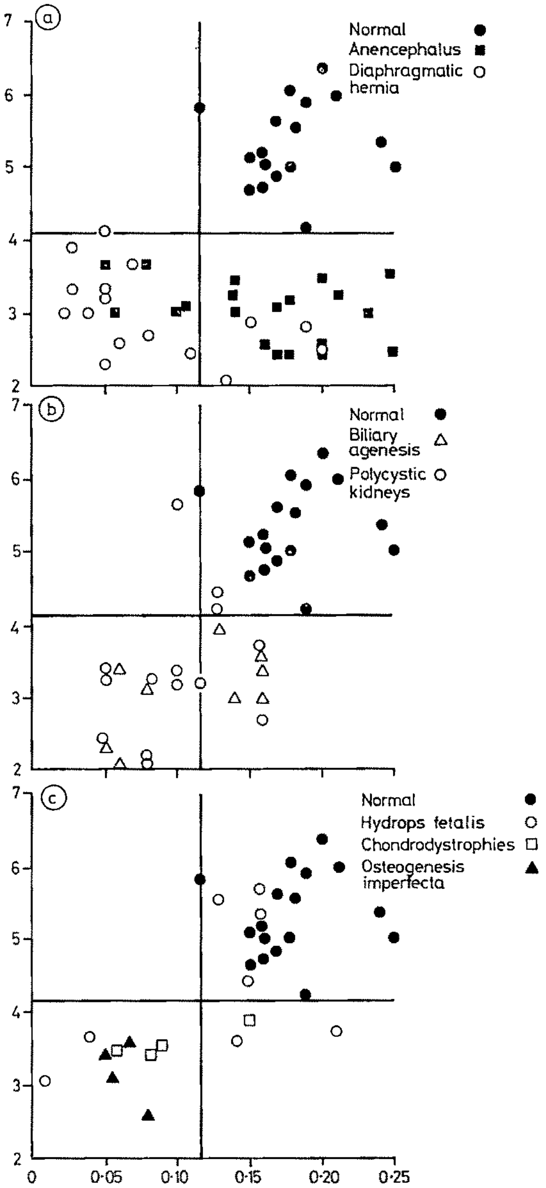

Figure *Comparison of lung weight:body weight ratio and radial alveolar count for each aetiological category as indicated. Values for individual patients are plotted according to absolute values of LW:BW ratio (abscissa, bottom), and mean RAC (ordinate, left). Additional horizontal and vertical lines, respectively, represent the values for the lower limits of normal for RAC and LW:BW ratio.*

With the exception of LW:BW ratios in anencephalics, LW:BW ratios and RAC were much reduced in each pathological group (Table). The results are illustrated graphically by plotting LW:BW ratios against RAC (Figure). Lines were drawn to indicate the lower limits of normal for each of the two parameters. The number of measurements below the normal range (mean −2 SDs) for each

Table *Lung weight; body weight ratios and radial alveolar counts in different aetiological categories*

10	Meconium peritonitis	37	2·8	1	—	—	0·012	1	—	—	3·8

P value for the differences of the means of each of the groups 2–6 and of group 1 was at least <0·01 for LW:BW ratio and <0·005 for RAC.

group was greater for LW:BW ratio than for RAC. The number of cases with values for both LW:BW ratio and RAC within the normal range is also given. Complementary use of the two criteria failed to detect PH in only a very few cases.

Discussion

Pulmonary hypoplasia is diagnosed in 7·8 to 10·9% of neonatal necropsies and in about half of necropsied neonates with congenital anomalies (Driscoll and Smith, 1962; Pryse-Davies, 1972; Sultana *et al.*, 1973), yet diagnostic criteria of PH have not been established. Whereas histological descriptions of PH have limited value (Potter, 1961; Reale and Esterly, 1973), the RAC provides a simple objective measurement of 'relative paucity of alveoli' or 'crowding of bronchial structures' which is unaffected by the state of expansion of the lungs (Emery and Mithal, 1960). At present PH is usually identified from associated anatomical diagnoses, such as those studied by ourselves. However, the diagnosis is often overlooked, especially when diagnostic associations are lacking. Moreover, a prejudiced diagnosis of PH may be made when anticipated from diagnostic associations.

Our results of LW:BW ratios and RAC are similar to those of Emery and Mithal (1960) when differences in the method (see Materials and Methods) are accounted for (RAC alveolar count = RAC alveolar septal count −1).

While we agree that typical histological changes of PH are due to quantitative rather than to qualitative factors (Reale and Esterly, 1973), we have reservations about anencephalus. We note a discrepancy between the LW:BW ratio and the RAC (Fig. 1a) which is only partially explained by a spuriously low body weight due to absence of the brain. With the exception of cases with associated thoracic skeletal anomalies (Potter, 1961), the pathogenesis of PH in anencephalus has never been satisfactorily explained. This inconsistency between LW:BW ratio and RAC suggests a specific delay in alveolar development, possibly related to the hypothetical role of the pituitary in lung growth (Jain *et al.*, 1973). Animal models of anencephalus produced at 0·6–0·7 of gestation do not appear to have fewer air sacs (Blackburn *et al.*, 1972; Meyrick *et al.*, 1975) but the validity of the model for study of lung growth throughout gestation is questionable.

Necropsy studies of lung development in diaphragmatic hernia are not fully representative of this condition, as patients with less severe PH survive. In survivors there is a tendency towards progressive improvement postoperatively but normal lung function values may never be attained (Chatrath *et al.*, 1971).

In the renal anomaly group the mean values for LW:BW ratio and the RAC were lower than those reported by Reale and Esterly (1973). This is explained by the fact that the latter study included unilateral renal anomalies, which are probably unassociated with PH (Perlman and Levin, 1974).

In our study we showed that PH is the probable cause of death in osteogenesis imperfecta congenita, presumably as a result of restriction of lung growth by the skeletal lesion, as occurs in chondrodystrophies (Finegold *et al.*, 1971). PH was also demonstrated in some instances of hydrops fetalis, as reported by Chamberlain *et al.* (1977), and may have been caused by the thoracic space-occupying effects of large pleural effusions and raising of the diaphragm by tense ascites and gross hepatosplenomegaly. It is suggested that a similar mechanism exists that raises the diaphragm in PH associated with ascites in meconium peritonitis.

There is fairly good agreement of reported normal values of lung weights or LW:BW ratios in different series (0·18–0·022) (Schultz *et al.*, 1962; Potter, 1972; Reale and Esterly, 1973), but by excluding lungs with oedema and exudates, Emery and Mithal (1969) arrived at a mean LW:BW ratio of 0·013. Normal lung weight is greatly influenced by postnatal absorption of lung fluid (Aherne and Dawkins, 1964). In spite of these limitations, an LW:BW ratio <0·012 suggested PH at all gestational ages in our material. This value was outside the range of our normal controls but was higher than half the normal mean (0·009) arbitrarily suggested by Potter (1972) as a criterion of PH. In those instances of PH discovered incidentally, a LW:BW ratio <0·012 led to confirmation of the diagnosis of PH by RAC, and in the light of this diagnosis the clinical and radiological manifestations were retrospectively made more comprehensible.

Data on the number of measurements of each parameter that came within the normal range (Figure) suggest that in each case, the RAC provides a clearer definition between PH and normal subjects than the LW:BW ratio. It should be pointed out that the difference between the mean normal RAC (5·3) and lower limit of normal (4·1) becomes greater when these values are raised to the third power (149 v. 69) in order to produce a 3-dimensional measure (i.e. number of alveoli in terminal respiratory units) from the single dimension that the RAC represents (Emery and Mithal, 1960).

We suggest the following guidelines for the diagnosis of PH. LW:BW ratio <0·009, PH very likely, RAC not obligatory. LW:BW ratio 0·010–0·012, PH probable, RAC indicated for confirmation of diagnosis. LW:BW ratio 0·013–0·017, PH possible, RAC desirable. LW:BW ratio >0·018, PH unlikely, and RAC probably not indicated. Where RAC is estimated, a value <75% of the mean normal value (equivalent to 43% of cubed value) for that laboratory probably indicates PH.

PH is rarely diagnosed in living patients but there is increasing awareness of this condition (Renert *et al.*, 1972; Leonidas *et al.*, 1975). The existence of a spectrum of lung hypoplasia has been recognised but this is not shown in a necropsy study owing to lack of representation of less severe or borderline PH patients who are excluded from study by virtue of their survival (De Lorimier *et al.*, 1967; Burkle and Bravo, 1969; Potter, 1972; Perlman *et al.*, 1975). Finally, the role of impaired lung growth in other neonatal pulmonary conditions—such as hydrops fetalis and even hyaline membrane disease—has not been fully explored.

We thank Professor E. Rosenmann for interpreting lung histology, and Professor B. Czernobilsky and Professor M. Sachs for access to material.

Neutrophil function in children with acute lymphoblastic leukaemia in the presence and absence of viral infections

M. M. REID, A. W. CRAFT, AND W. T. LOW

Royal Victoria Infirmary, Newcastle upon Tyne

SUMMARY Neutrophil function was assessed regularly in 26 children with acute lymphoblastic leukaemia (ALL) in remission, both when they were well and during viral infections. Tests of candidacidal ability when these children were apparently free of infection showed a trend towards lower levels compared with controls. The most pronounced depression of candidacidal ability and chemotaxis was during viral infections, and these two functions of neutrophils were more likely to be abnormal then than when the children were free of infection. In children with ALL in remission, whose neutrophils may function abnormally even when they are well, the risk of acquiring bacterial or fungal infections may be made greater by virus infections.

Infection is a major cause of death for children with ALL, particularly during remission (Hughes 1971; Craft *et al.*, 1977). Although viruses are increasingly being incriminated in the deaths of such children, overwhelming bacterial or fungal infections still account for many deaths. Profound neutropenia is not always associated with such deaths. Several of the deaths recently reported from Newcastle were associated with coexistent viral and bacterial infections (Craft *et al.*, 1977). The interaction of such infections is poorly understood. As part of a larger survey of infection and immunity in children with ALL in remission, neutrophil function was assessed to discover whether any defects were detectable and, if so, whether they could be related to the presence of infection.

Patients

Between June 1975 and October 1976, 27 children with ALL presenting consecutively to one of two major hospitals in Newcastle upon Tyne were entered into the study. Their ages at diagnosis ranged from one to 10 years. One patient died before remission was induced. The remaining 26 patients were followed up, while in remission, for periods ranging from 4 months to 2 years. All were receiving a modified version of an ALGB 6801 regimen (Reid *et al.*, 1977). The children were assessed if possible at regular monthly intervals and when infection was suspected. At times, insufficient blood was obtained and some tests could not be performed. Routine testing was not carried out at diagnosis because it was usually impossible to obtain adequate numbers of neutrophils.

Controls

Neutrophil function tests were controlled with cells from laboratory staff. Reference ranges were derived from results obtained from 20 staff members and from 6 children, aged 3 to 11 years, admitted to hospital with noninfective conditions.

Methods

Neutrophils were separated by centrifuging white blood cell-rich plasma from dextran-sedimented blood over a Ficoll-Triosil (Lymphoprep, Nygaard) gradient.

Stimulated nitrobluetetrazolium (NBT) reduction was assessed on whole blood samples by the method of Segal and Peters (1975). Results were expressed as arbitrary spectrophotometer units/10^6 neutrophils.

Chemotaxis was assessed by a method based on that of Wilkinson (1974). Results were expressed as

the distance in μm travelled by the leading front of neutrophils into the micropore filter.

Killing ability was assessed using *Candida albicans* as the test organism by a method based on that of Goldman and Th'ng (1973). Results were expressed as the percentage of *C. albicans* killed.

Virus infections were diagnosed by immunofluorescent techniques and culture (Gardner and McQuillin, 1974).

During the period of the survey there was no occasion on which adequate numbers of neutrophils were obtained from children with bacterial or fungal infections.

Results

The results of tests of NBT reduction, killing ability, and chemotaxis in the children with ALL, both in the presence and absence of virus infections, are shown in Figs 1, 2, and 3. The reference adult and child

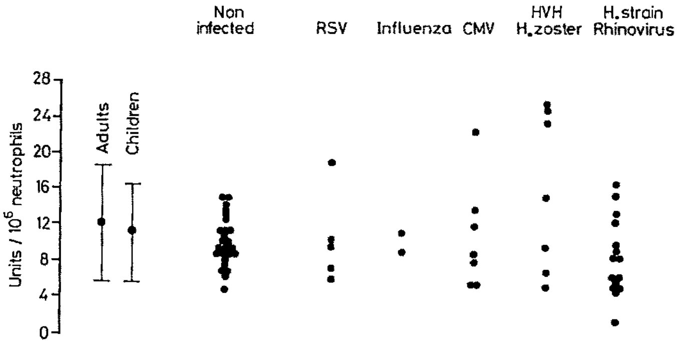

Fig. 1 *Stimulated NBT reduction in children with ALL when well and during virus infections with reference ranges (mean ± SD) for children and adults.*

Table 1 *Killing ability. Summary of 'normal' and 'abnormal' results in noninfected and infected children with ALL*

	Noninfected	*Infected*
Normal tests	96	14
Abnormal tests	47	17
Totals	143	31

Table 2 *Chemotaxis. Summary of 'normal' and 'abnormal' results in noninfected and infected children with ALL*

	Noninfected	*Infected*
Normal tests	134	21
Abnormal tests	22	12
Totals	156	33

ranges are given for comparison. Each point in the noninfected group represents a mean of all tests performed in an individual child when no infection could be detected. One of the 26 children was at no time tested when free of infection. All other points represent the results of a single test. The mean value of killing ability (±SD) in the children with ALL when they were free of infection is 19% (±4). The reference adult range is 25% (±6). This difference is significant (Student's t, $P<0\cdot01$).

Tables 1 and 2 give a summary of the results of all the individual tests of killing ability and chemotaxis. Results which are described as 'abnormal' are all below the lowest point on the reference ranges for the appropriate test. Killing ability was more likely to be 'abnormally' low (<18%) in infected than noninfected children ($\chi^2 = 5\cdot3$, $P<0\cdot05$). Chemotaxis was also more likely to be 'abnormal' (<84 μm) in infected children ($\chi^2 = 4\cdot6$, $P<0\cdot05$).

There was no obvious change in the pattern of results with time, nor did the stage of treatment appear to affect them.

Discussion

There was no difference in NBT reduction and chemotaxis between the control populations and the children with ALL when not infected. However the results of tests of killing ability in such children (Fig. 2) suggest there was some impairment, as there was a trend towards lower levels than was found in the normal population. Quantitative assessment of killing ability is simplified if *C. albicans* is used as the test organism. It is probably killed by the hydrogen peroxide mechanism, as are many bacteria.

However, tests of candidacidal ability may not be comparable with those of bactericidal ability. Few defects in neutrophil function during remission of ALL have been reported. Strauss *et al.* (1970) reported a bactericidal defect in 4 of 6 patients in remission. Gregory *et al.* (1972) described a bactericidal defect in a group of children most of whom were in remission. Baehner *et al.* (1973) found a temporary bactericidal defect associated with craniospinal irradiation, but not at any other time in remission. Sarab-el-Nakeeb and Thompson (1977) reported abnormal chemotaxis in children with ALL in remission. Bactericidal defects have also been described during relapse of ALL (Strauss *et al.*, 1970; Humbert *et al.*, 1976).

Depression of neutrophil function by viruses in normal subjects has been demonstrated *in vitro* (Larson and Blades, 1976; Larson *et al.*, 1977; Ruutu *et al.*, 1977). Normal children with virus infections also have abnormally functioning neutrophils (Anderson *et al.*, 1976; Craft *et al.*, 1976). The present study did not show significant depression of NBT reduction in children with ALL by virus infections. However a striking depression of killing ability and chemotaxis in some of these children took place during virus infections.

Virus infections may therefore be associated with depression of neutrophil function in a group of children whose neutrophils may already be adversely affected by their leukaemia or by treatment. This depression of function, in addition to the risks of neutropenia, may make children with ALL even more susceptible to bacterial and fungal infections, and shows the seriousness of comparatively common viruses to such children.

Intrathecal serotherapy in neonatal tetanus: a controlled trial

M. R. SEDAGHATIAN

Department of Paediatrics, Pahlavi University, School of Medicine, Shiraz

SUMMARY 60 infants with neonatal tetanus were treated at random either by 40 000 units of equine tetanus antitoxin (TAT), intravenously and intramuscularly, or by 40 000 units TAT, IV and IM, plus 150 units of human tetanus immune globulin (TIG) intrathecally. There were 30 infants in each treatment group. Babies were similar in age, sex, weight, incubation period, temperature, and signs and symptoms on arrival at the hospital. The mortality rate, days in hospital, and days of sedation were not significantly different in the two groups.

Tetanus is still a major health problem in developing countries both in incidence and mortality. The mortality is particularly high in neonates (Nourmand *et al.*, 1970; Salimpour, 1977).

Although equine tetanus antitoxin (TAT) has been used to treat this disease for many years, the preferred dose, efficacy, and route of administration are not clear (Brown *et al.*, 1960; Athavale and Pai, 1966). The present tendency is to give a single dose of TAT initially (McCracken *et al.*, 1971). In children 20 000 to 100 000 units have been used (Spaeth, 1941; Brown *et al.*, 1960). It was suggested that intrathecal administration of tetanus immune globulin (TIG) together with corticosteroids reduced the mortality in neonates (Ildirim, 1967, 1974). The purpose of this report is to evaluate intrathecal administration of 150 units of TIG without corticosteroids in the treatment of tetanus neonatorum.

Patients and methods

During the 50-month period from January 1974 to February 1978, 64 newborn infants with the clinical diagnosis of tetanus were admitted to the newborn unit of Nemazee Hospital, Shiraz, Iran. This unit admits all sick neonates from Shiraz and the surrounding area, altogether a population of about 600 000. The diagnosis was made clinically by M.R.S.

All newborn babies in this prospective study were alternately assigned to one of two treatment groups. The control group received 20 000 units of TAT IV and 20 000 units IM in the first few hours after admission. The study group received the same amount of TAT by the same routes, plus 150 units of TIG intrathecally.

Blood cultures and spinal taps were performed in both groups of babies.

Valium (15 mg/kg per day) was given initially intravenously and then by nasogastric tube. If the valium failed to control the convulsions, chlorpromazine (Largactil) 2–3 mg/kg per day was added.

Initially, all babies were given benzylpenicillin 50 000 to 100 000 units/kg per day and gentamicin 5 to 6 mg/kg per day in two divided doses. Benzylpenicillin was continued for 10 days, but gentamicin was stopped after 5 days if the spinal fluid and blood cultures remained negative.

Each infant was admitted to a separate room. The umbilical area was thoroughly cleaned. Nasogastric tube feeding was initiated as soon as the baby's convulsions were under control.

Age, sex, weight, incubation period, rectal temperature, clinical symptoms, and signs of pneumonia were recorded for each baby at the time of admission. Days in hospital, days to death, days of sedation, and mortality for both treatment groups were recorded.

Results

Of 64 neonates with the clinical diagnosis of tetanus, 60 were admitted to the trial, 30 in each treatment group. Four patients were excluded within the first 3 days: 2 because of associated meningitis and 2 because they had received some TAT before arrival at the hospital.

Department of Paediatrics, Nemazee Hospital, Shiraz, Iran
M. R. SEDAGHATIAN, assistant professor of paediatrics

All infants had been delivered at home with the help of unqualified midwives. 14 (23%) of 60 were from Shiraz and the rest came from villages nearby.

There were 2 preterm babies and one term small for gestational age (SGA) infant in the control group, and one term SGA infant in the study group. Table 1 shows the main signs and symptoms in these babies on admission. Table 2 compares various characteristics in the two groups.

The two groups were comparable for sex, age, weight, incubation period, temperature on admission, days in hospital, days of sedation, days to death, and number dying. There was no significant difference in survival rate between the two groups.

There were 2 babies, one in each group, who recovered from tetanus but died from other causes. One died 60 days after admission from gastroenteritis, urinary tract infection, and hydronephrosis and the other baby died 30 days after admission from hepatitis and septicaemia. The days to death for these 2 patients are excluded from the analysis.

Table 1 *Signs and symptoms in both groups of babies on admission*

Signs and symptoms	*Study group*	*Control group*	*Total (n = 60)*
Refusal to feed	29 (97)	29 (97)	58 (97)
Convulsion (tetanic spasm followed by clonic movement)	28 (93)	28 (93)	56 (93)
Trismus	27 (90)	26 (87)	53 (88)
Generalised rigidity on arrival	28 (93)	22 (73)	50 (83)
Cyanosis	18 (60)	20 (67)	38 (63)
Irritability	18 (60)	16 (53)	34 (57)
Respiratory distress	17 (57)	12 (40)	29 (48)
Opisthotonus on arrival	15 (50)	14 (47)	29 (48)
Poor reflexes	5 (17)	5 (17)	10 (17)
Risus sardonicus	2 (7)	2 (7)	4 (7)

Percentages are given in brackets.

Table 2 *Summary of various characteristics of the two groups*

Characteristics	*Study group (n = 30)*	*Control group (n = 30)*
Mortality	13 (43)	15 (50)
Age on admission (days)	9·5 ± 8·5*	8·9 ± 7·8*
Sex		
Male	26 (87)	25 (83)
Female	4 (13)	5 (17)
Weight (g)	3025 ± 906*	2878 ± 995*
Incubation periods		
<7 days	22 (73)	21 (70)
8–14 days	8 (27)	9 (39)
Rectal temperature on admission		
<37·5°C	13 (43)	13 (43)
37·6–39·0°C	11 (37)	11 (37)
>39·1°C	6 (20)	6 (20)
Days in hospital for survivors	26·7 ± 19·6*	26·8 ± 28·5*
Days sedated for survivors	21·8 ± 12·7*	25·2 ± 14·4*
Days to death	5·2 ± 7·3*	6·4 ± 10*

Percentages are given in brackets.
*Mean ± 2 SD.

Table 3 *Mortality rate according to incubation period*

Incubation period	*Study group (n = 30)*	*Control group (n = 30)*
Up to 7 days	11/22 (50)	13/21 (62)
8–14 days	2/8 (25)	2/9 (22)
Total mortality	13 (43)	15 (50)

Percentages are given in brackets.

The mortality rate according to incubation period is shown in Table 3. The death rate for incubation periods less than 7 days was slightly higher in the control group, 13 (62%) of 21, than in the study group, 11 (50%) of 22.

There were 12 (40%) of 30 babies in the study group and 8 (27%) of 30 in the control group who showed some sign of pneumonia on admission.

Discussion

The intrathecal administration of TAT for treatment of tetanus began early in the 20th century. The first trial was by von Leyden in 1901, and then there were trials by Penna in 1902 and Rogers in 1905. Because of fatal complications of intrathecal TAT administration and no obvious change in survival rates, this treatment was stopped (Dietrich, 1940; Pratt, 1945).

Ildirim (1974) used intrathecal TAT or TIG, combined with corticosteroids, with good results in tetanus neonatorum. At the Fourth International Congress on Tetanus in 1975, it was felt that serious consideration should be given to this method of treatment (Furste, 1976). The amount recommended was a single injection of 250 units of TIG mixed with 12·5 mg prednisolone, given intrathecally. 2500 units of TAT were given both IM and IV, plus 10 mg prednisolone in two divided doses orally. A mortality rate between 14·8 and 20% was reported (Ildirim, 1974). However, the relative importance of each component of this treatment remained to be established. Therefore, we used intrathecal TIG without corticosteroids, choosing a dose of 150 units because we were giving 40 000 units of TAT by other routes. The results in the study group showed no advantage in this treatment (Table 2).

As intrathecal TIG did not alter the mortality rate for this disease, good results in other studies may be attributed to corticosteroids, to a higher dose of intrathecal TIG, or possibly, to synergism. A controlled trial of intrathecal corticosteroids without TIG is now in progress.

Any conclusion about therapy must be guarded since Chen (1974) showed that good nursing care can reduce the mortality rate to 20%.

I should like to thank Dr Paul A. Steinman for his useful suggestions and guidance in the preparation of this report, and Dr A. Madani for collecting some of the data.

Current topics

A suggested child-health clinic form

R. S. ILLINGWORTH

Children's Hospital, Sheffield

After more than 30 years' experience of baby clinics, first in an obstetrics hospital and more recently in Area Health Authority clinics, I am convinced that there is a need for a suitable form for the use of clinic doctors and health visitors, and for family doctors who have their own child health clinics. I believe that the form I have designed provides a good basis.

The assessment, and the form recording it, must be simple and practical. An assessment which takes about 30 minutes is certainly necessary in special circumstances if there is difficulty in the diagnosis, but it is impractical in a busy clinic with babies and children awaiting immunisation, or assessment, or both. Hence all irrelevant developmental features—interesting as they are, and sometimes important for difficult cases—must be eliminated. Milestones and tests should be strictly confined to those that matter, those which are extremely unlikely to miss any significant abnormality.

As in a passport form, application for life insurance, or VAT assessment form, each question must be answered and so must be capable of being answered. For instance, it is useless in the 6-week assessment to include the word 'reflexes', as is currently done in a commonly used form; the clinic doctor cannot be expected to know which of the 70 or so primitive reflexes is relevant, and he therefore has to decide whether to insert a 'yes' or 'no', or a tick or a cross. He almost always inserts a tick, hardly an informative answer.

In a much used school clinic form, there is the heading:

Development, hernia	☐
Other	☐
Psychological development	☐
Stability	☐

Children's Hospital, Sheffield
R. S. ILLINGWORTH, emeritus professor of child health

In my form, there are spaces with headings which anyone can understand: they are 'normal', 'doubtful', 'abnormal', with a space for explaining why the finding may be abnormal.

I have left no space for an overall score, in the form of a figure. Some features of a child's development—especially his alertness, responsiveness, and interest in surroundings—are much more important than others. It is not the place of a clinic doctor to attempt to calculate an IQ score: but he is required to separate the normal from the abnormal, to detect the child who calls for special investigation by an expert. I have avoided defining the range of normal, for it is never possible to insert the exact dividing line between normal and abnormal.

I have sketched the principal features of motor and manipulative development because many doctors and health visitors like to have such a guide (Illingworth, 1977). For the same reason I have given the average age at which milestones are reached, using Gesell's figures. For further information about these see Illingworth (1979).

My intention is that all the information will go on a 6-sided firm card, similar to the one now often used in clinics. I would welcome suggestions for its improvement, but the form must not be lengthened.

Permission was obtained from Blackwell Scientific Publications for reproduction of the sketches.

Short reports

Neonatal small left colon syndrome

L. RANGECROFT

Hospital for Sick Children, Newcastle upon Tyne

SUMMARY Five patients with neonatal small left colon syndrome are described together with some early investigative studies on rectal biopsy material. Current reports on this condition are reviewed. The precise aetiology remains unknown, but vigilance and early referral are recommended in view of the several reports of colonic perforation.

Delay in diagnosis and treatment can result in serious complications in the otherwise benign neonatal small left colon syndrome. This condition was first distinguished from other forms of microcolon by Davis *et al.* (1974), and subsequently reports have suggested a surgical orientation. The condition presents as a low obstruction of the large bowel, similar to Hirschsprung's disease in the newborn. There is failure to pass meconium, with tympanitic distention of the abdomen and bilious vomiting.

Contrast radiography, particularly with Gastrografin, shows a smooth, narrow sigmoid and descending colon, with proximal dilatation of the large bowel. However, the enema also promotes both the rapid evacuation of meconium and the early establishment of normal defecation. Many of the mothers of such babies have diabetes mellitus.

A group of 5 babies illustrates the practical management of the condition; 2 of them are described in detail.

Case reports

Case 1. A baby boy, weighing 2·65 kg, delivered normally at 37 weeks. There was no history of maternal diabetes. He failed to pass meconium and was transferred at 30 hours with tympanitic abdominal distention and bile-stained vomiting.

Plain *x*-rays of the abdomen showed dilated loops of small and large bowel, with multiple fluid levels consistent with a low obstruction of the large bowel (Fig. 1). A Gastrografin enema was performed to assist radiological diagnosis. This showed a smooth, narrow descending and sigmoid colon with a marked 'transition zone' to distention at the splenic flexure (Fig. 2). The colon proximal to the splenic flexure was overfilled with air and meconium. These appearances are typical of the neonatal small left colon syndrome but simulate long-segment Hirschsprung's disease. The latter diagnosis was made in error, and a left transverse colostomy established. Subsequent investigations showed no evidence of Hirschsprung's disease and at 11 months the colostomy was closed. The infant has remained well since.

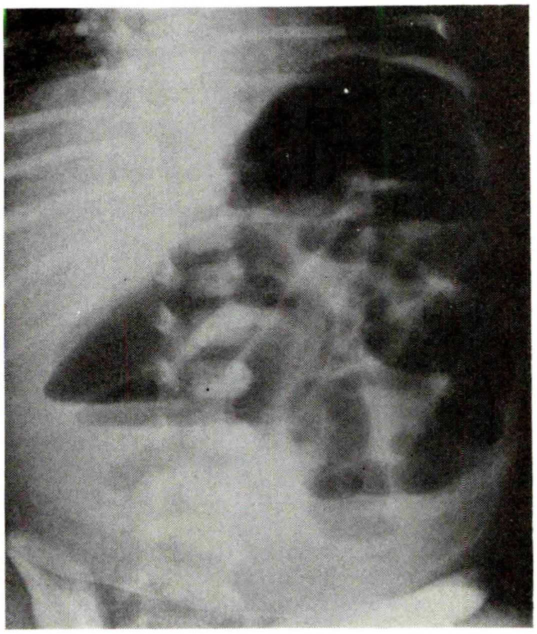

Fig. 1 *Erect abdominal x-ray showing multiple fluid levels in dilated small and large bowel.*

Case 2. A baby girl weighing 3·4 kg of a diabetic mother, delivered by forceps at 36 weeks' gestation. She was referred at 24 hours with failure to pass

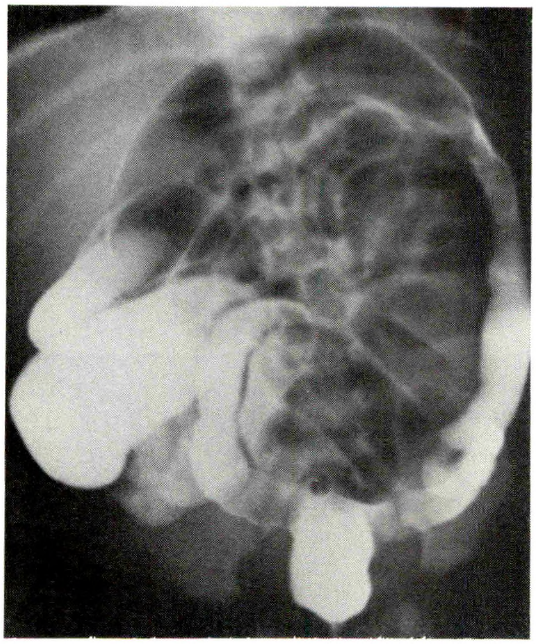

Fig. 2 *Gastrografin enema showing narrowed descending and sigmoid colon and transition zone at splenic flexure.*

meconium, tympanitic abdominal distention, and bile-stained vomiting. Plain *x*-rays indicated a low colonic obstruction and a Gastrografin enema showed the typical appearances of the small left colon syndrome.

Evacuation of meconium followed rapidly and subsequent bowel function was normal. No further investigations were made and the baby has remained well.

Three other infants were seen in whom the history and progress were similar to Case 2, although none was known to have a diabetic mother. Further description of the clinical details is redundant but the results of investigations undertaken to exclude Hirschsprung's disease are of interest.

In Case 1 quantitative estimations of total cholinesterase activity were made in rectal biopsy specimens, using the method described by Boston *et al.* (1975). At 72 hours, the value was in the high normal range (21·8 rate units) and barely excluded Hirschsprung's disease but, when it was repeated at 2 weeks, the result was unequivocally normal (10·0 rate units). In 2 of the other patients, estimations were done for total cholinesterase and acetyl cholinesterase, using the method described by Dale *et al.* (1977). In one, the results were normal at 4 days, but in the other patient, in whom the quantity of enzyme present was also normal, the ratio of acetyl cholinesterase to total cholinesterase was 82% which is consistent with Hirschsprung's disease. This estimation was performed at 3 days, but repetition was not justified in view of the patient's good progress.

Discussion

Sluggish or delayed passage of meconium in the newborn is well recognised, and there are various reasons for this condition. Two of the causes to be distinguished from the small left colon syndrome are the meconium plug syndrome (Clatworthy *et al.*, 1956), and long segment Hirschsprung's disease.

The small left colon syndrome is distinct from either as there is no meconium plug and the intrinsic neurohistology of the affected bowel is apparently normal. In the first description of the syndrome (Davis *et al.*, 1974) 20 infants were reported, 2 of whom were operated on as suspected of having Hirschsprung's disease. One other patient died soon after birth of hyaline membrane disease. After administration of a diagnostic barium enema, all the remaining 17 patients began and continued to evacuate their bowels normally. Eight of them had diabetic mothers and this high correlation has subsequently been confirmed (Davis and Campbell, 1975; Philippart *et al.*, 1975; Stewart *et al.*, 1977). Later reports have not agreed with the initial opinion that complications are rare. Philippart *et al.* (1975) and Stewart *et al.* (1977) reported that in 4 babies out of 12 there were perforations of the bowel. These perforations are often in the caecum and, in one baby, this was 6 days after a barium enema. For this reason vigilance is recommended before *x*-ray examination with contrast enemas is undertaken, and early referral of these patients to paediatric surgical centres for diagnosis and treatment is to be preferred.

The aetiology of the small left colon syndrome is obscure. No abnormality of meconium has so far been shown and it is unusual for a meconium plug to be passed (Clatworthy *et al.*, 1956; Ellis and Clatworthy, 1966).

Davis *et al.* (1974) reported that in biopsy material from 4 babies increased numbers of immature small cells were noted in the myenteric plexus, and these were present in both the narrow and dilated areas of colon. These findings were confirmed by Stewart *et al.* (1977) but not by Philippart *et al.* (1975), and none of the biopsy material now reported has shown any gross abnormality in the intramural ganglion cells and nerves, but studies of the cholinesterase suggest a temporary ganglion cell dysfunction.

Philippart *et al.* (1975) confined their attention to the children of diabetic mothers and suggested that the problem in the infant results from impaired intestinal motility, possibly promoted by glucagon, rather than from an intraluminal plug. In several of their patients an element of obstruction persisted after complete evacuation of meconium and it has been shown that the small calibre of the left colon can persist for variable periods despite normal bowel activity (Davis *et al.*, 1974). Their hypothesis is that an increase in glucagon excretion occurs in babies in the perinatal period either secondary to hypoglycaemia associated with maternal diabetes in a complex way, or with stress. Glucagon is known to decrease bowel motility in the jejunum and sigmoid colon. Conversely hypoglycaemia can also increase bowel motility by vagal and sympathetic stimulation, and consequently Stewart *et al.* (1977) have proposed that the immature small intramural nerve cells are unable to respond to increased sympathetic stimulation. The results of further studies are awaited.

I wish to thank Mr J. E. S. Scott and Mr J. Wagget, consultant paediatric surgeons, for permission to study their patients.

Acute necrotising fasciitis due to streptococcal infection in a newborn infant

J. NUTMAN, E. HENIG, E. WILUNSKY, AND S. H. REISNER

Departments of Neonatology and Microbiology, Beilinson Medical Centre, and Sackler School of Medicine, Tel-Aviv University, Israel

SUMMARY A 3-day-old baby girl developed septicaemia, meningitis, and necrotising fasciitis due to group A β-haemolytic streptococcus, type M52, which was also cultured from the mother's cervix. Necrotising fasciitis is a severe infection of the skin and subcutaneous tissues with infarction, necrosis, and sloughing of the affected areas. Early recognition of this condition is essential so that appropriate treatment can be given.

Acute necrotising fasciitis is a rare but severe bacterial infection of the subcutaneous tissue and fascial planes, producing extensive destruction of tissues (Hammar and Wagner, 1977). It is often associated with blood stream invasion by the causative pathogen, and the mortality is high. The condition is familiar to the surgeon, but it appears to be rare in children (Wilson and Haltalin, 1973), and only 3 cases have been reported in newborn infants (Weinberger *et al.*, 1972; Ramamurthy *et al.*, 1977).

We report a newborn infant who developed septicaemia, meningitis, and necrotising fasciitis caused by group A β-haemolytic streptococcus.

Case report

A term baby girl of 2·7 kg was born to healthy non-related parents after a pregnancy complicated only by a heavy leucorrhoea during the 3rd trimester. The membranes ruptured spontaneously 14 hours before a normal delivery. The Apgar score at one minute was 9, and the initial examination was normal. On the 3rd day of life it was noted that she nursed poorly, and an erythematous lesion was observed on the right cheek. Within a few hours the baby's condition deteriorated. She became apathetic, comatose, and her rectal temperature rose to 39·5°C. The rash had spread to the scalp, the back of the neck, and the left upper arm. Initially the rash was indurated, erythematous, and warm. No regional lymphadenitis was noted. A severe infection was suspected.

The blood count showed a leucopenia of $1\cdot 5 \times 10^9$/l and a thrombocytopenia of $55\cdot 0 \times 10^9$/l. The next day the leucocyte count increased to $29\cdot 6 \times 10^9$/l with 39% band cells and 5% metamyelocytes. Chest *x*-ray and urine analysis were normal. The spinal fluid was bloody. Cultures from the nose, skin, CSF, blood and from the mother's cervix grew β-haemolytic streptococcus group A, type M52. A repeat lumber puncture 2 days later showed clear CSF with cells $0\cdot 028 \times 10^9$/l (mainly polymorphonuclears), a protein level of 220 mg/100 ml (2·2 g/l), and glucose of 47 mg/100 ml (2·6 mmol/l). The culture was negative.

Treatment was immediately started with IV penicillin, gentamicin, and chloramphenicol, and a double volume exchange transfusion was performed. When the results of the cultures were received treatment was continued with only penicillin and frequent transfusions of blood and plasma.

The infant's condition improved rapidly. She became alert and responsive. However, the skin rash changed to a dusky bluish-grey colour, vesicles appeared, and the rash spread along the fascial planes of the upper arm. Subsequently the skin became a purplish colour in some areas and extremely indurated (Fig. 1). The same process was seen in the neck but the rash on the right cheek and the scalp faded.

Gradually areas of necrosis appeared on the skin of the neck and left upper arm and the skin sloughed (Fig. 2). Debridement was performed and the skin was treated with dilute solutions (0·5%) chlorinated lime and boric acid solution (BPC) dressings. Granulation tissue appeared very slowly and it was therefore decided to treat the skin of the arm with pig skin treated with glutaraldehyde. There was rapid growth

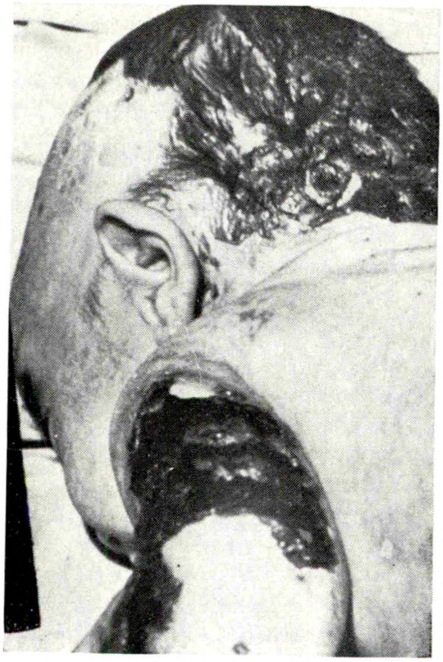

Fig. 2 *Necrotic areas of skin on left upper arm.*

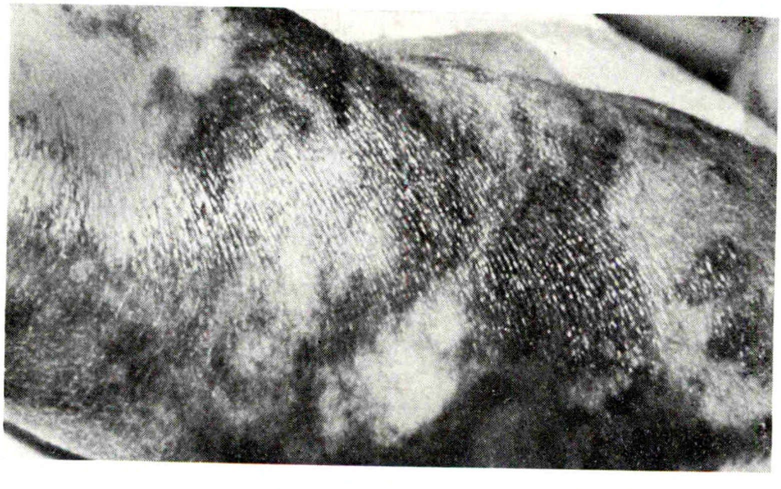

Fig. 1 *Lateral view of left upper arm showing the marked induration of the skin with areas having a purplish-black colour.*

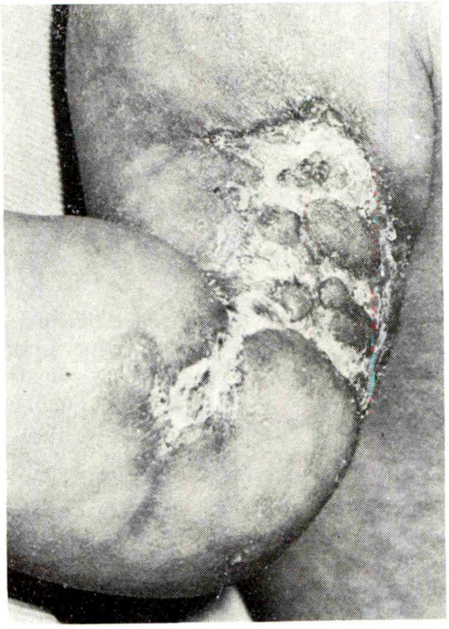

Fig. 3 *Scarring and cicatrisation of skin on left upper arm.*

of granulation tissue and the skin healed with good scarring (Fig. 3). No side effects were noted from the treatment with boric acid solution. The infant was discharged at age 2 months in good health; she was neurologically normal.

Discussion

Streptococcal septicaemia in neonates is usually associated with strains of Lancefield group B. Although no longer the scourge of maternity units, group A streptococci can still cause severe neonatal infection (Peter and Hazard, 1975). The infant may be infected by the mother who carries the streptococcus in her respiratory tract or in her vagina, as was the case in this infant, or by hospital staff.

Group A streptococcus is the most common cause of necrotising fasciitis, although other Gram-positive or Gram-negative organisms have also been reported. Joseph Jones (1871), an army surgeon during the American Civil War, first described this condition. Meleney (1933) gave a clear description of it. The area first becomes swollen, erythematous, warm, and painful. Unlike erysipelas, the border is not raised or well defined and the development of lymphangitis or lymphadenitis is unusual. The overlying skin develops a dusky bluish-grey colour and vesicles may appear. Fluid aspirated from these vesicles may be clear or turbid and usually contains the infecting organisms. The infection spreads rapidly along the fascial planes producing thrombosis of nutrient vessels with resultant necrosis of the overlying subcutaneous tissue and sloughing of the skin. Although the infection usually begins in an operative wound, it may develop without any apparent cause. Unchecked the process spreads rapidly, leading to debility, septicaemia, metastatic abscess, and death.

Therapeutic success depends on prompt recognition of the syndrome, early isolation of the infecting organism, treatment with appropriate antibiotics, vigorous debridement of superficial necrotic tissue, and incision of deep fascia to drain the underlying exudate. Supportive therapy with frequent transfusions of blood and plasma is essential. In our patient there was a rapid response to antibiotic treatment and the infant's general condition greatly improved. After debridement there was, however, very little granulation tissue formation and it was necessary to cover the area of the left upper arm with porcine skin. This resulted in rapid formation of granulation tissue and cicatrisation of the wound.

The infant was discharged at age 2 months, and at one year was found to be normally developed.

We thank Dr S. Rabinowitz, Streptococcus Reference Laboratories of the Ministry of Health, for the typing of the bacterial strains.

Subacute sclerosing panencephalitis after drug-induced immunosuppression

J. B. S. COULTER, NICOLA BALCH, AND P. V. BEST

Departments of Child Health and Pathology, University of Aberdeen

SUMMARY A girl developed subacute sclerosing panencephalitis (SSPE). Eight years earlier she had had measles infection contracted shortly after cytotoxic treatment and radiotherapy for a spinal neuroblastoma. The case illustrates that typical SSPE, like immunosuppressive measles encephalopathy, can arise after drug-induced immunosuppression, and supports the view that these diseases probably represent opposite ends of a spectrum induced by measles virus infection in an individual with some form of immunological deficiency.

Immunosuppressive measles encephalopathy (IME) is the term suggested by Pullan *et al.* (1976) for the rapidly progressive form of measles encephalitis in children who contract measles during immunosuppressive treatment. The neurological disorder develops 5 weeks to 6 months after measles infection and was first described by Lyon (1972). One way in which subacute sclerosing panencephalitis (SSPE) differs is that the interval between measles and the encephalopathy is much longer (average 6·6 years, Bellman and Dick, 1977) and we have found only one account of an SSPE-like illness after immunosuppressive treatment (Loirat *et al.*, 1971). We report a girl who contracted measles shortly after having received cyclophosphamide and radiotherapy for a neuroblastoma and who developed typical SSPE 8 years later.

Case report

The girl, born in Morayshire in July 1967 after an uneventful pregnancy and labour, developed paraplegia in November 1967 due to an extradural neuroblastoma at T9. She was in Adelaide, South Australia, at that time and after surgical decompression of the cord, a course of radiotherapy totalling 3500 rads was administered to a field extending from T7 to L4 inclusive. Cyclophosphamide was given in a dose of 3 mg/kg per day from 18 March to 27 August 1968. Treatment was interrupted twice for short periods because of neutropenia and was finally stopped owing to recurrence of neutropenia and anaemia. In late September she contracted measles from her elder sister but the illness was mild. She had not had measles immunisation.

The family returned to the UK in 1969. The patient's paraplegia was permanent and an ileal diversion was fashioned in 1971 because of urinary incontinence. Cycloserine 125 mg daily was given from 1971 to 1977 prophylactically for urinary tract infection.

In June 1977 the girl was referred to the neurology clinic because of deterioration in school performance, and lack of co-ordination and dressing skills during the previous 4 months; before this she had made good progress at school and had walked well with the aid of crutches and calipers. The only abnormality found apart from the paraplegia was slight incoordination of the left hand. The fundi were normal. When seen in August the patient was found to have suffered further deterioration in intellectual function and was reported to have had brief 'absences' accompanied by drooping of the left side of her mouth and a tendency to fall to the left. Her left arm now had a slight tremor and was weak. Treatment with sodium valproate was begun. In October she was admitted to hospital and by then had deteriorated markedly with spasticity of both upper limbs, especially the left, myoclonic jerks on this side, and epilepsia partialis continua of the left arm and left side of the face. She died 3 weeks later, 8 months after her initial symptoms.

Investigations

Urine (July 1977) vanillylmandelic acid and catecholamines normal: 17-hydroxycorticosteroids 20 µmol/24 h (5·8 mg/24 h), 17-ketosteroids 9 µmol/24 h (2·6 mg/24 h). Skull and chest *x*-rays normal. CAT brain scan (September 1977) showed dilatation of the 4th ventricle and slight enlargment of the pontine cisterns and cisterna magna, the appearances suggesting cerebellar atrophy. Blood (October 1977) Hb 11·8 g/dl, WBC 4·8 × 10^9/l with normal differential, urea 6·6 mmol/l (39·6 mg/100 ml), electrolytes normal. Measles serum complement fixation titre (CFT) 1:16 384; IgM specific for measles 1:12. Serum immunoglobulins: IgG 12·0 g/l, IgA 2·4 g/l, IgM 2·5 g/l. Plasma cortisol at 2200 hours 760 nmol/l (27 µg/100 ml), at 0800 hours 680 nmol/l (25 µg/100 ml). CSF cells normal, protein 0·44 g/l (44 mg/100 ml), IgG 0·108 g/l (10·8 mg/100 ml), measles CFT 1:128. EEG showed a generalised high voltage theta/delta wave activity with periodic higher voltage slow wave complexes, which at times had a notched appearance, occurring every 5–6 seconds; these arose predominantly over the right hemisphere initially but were more symmetrical in a later EEG.

Necropsy

Both legs were severely wasted and there was pronounced kyphoscoliosis. The ileal bladder contained a small amount of clear urine which readily refluxed into dilated ureters and there was bilateral hydronephrosis. Histological studies showed chronic pyelonephritis, centrilobular liver cell necrosis, and bronchopneumonia. Neither local recurrence of neuroblastoma nor metastases was identified. The lower lumbar and sacral regions of the spinal cord were completely atrophic and immediately above this area a 1·5 cm length of the upper lumbar cord was slightly expanded by greyish gliosis. The brain was externally unremarkable but transection after fixation showed slight induration and pinkish grey discoloration of the cerebral white matter, especially in the occipital lobes.

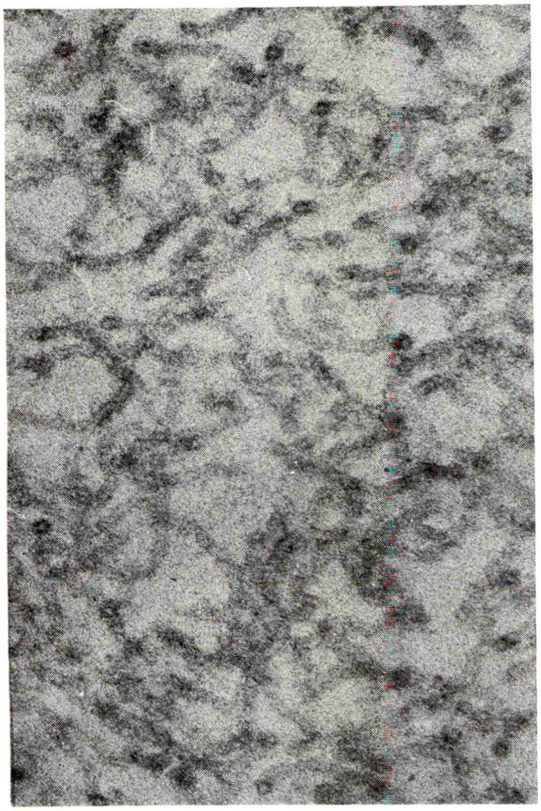

Figure *Electron micrograph showing intranuclear microtubules. × 128 000.*

The histological features of the brain were typical of SSPE with extensive subacute inflammatory changes affecting both grey and white matter. The main characteristics were perivascular cuffing by small mononuclear cells, mainly lymphocytes, depletion of myelinated fibres in white matter accompanied by conspicuous astrocytic gliosis, degeneration and fall-out of neurones, with various degrees of reactive microglial proliferation and frequent intranuclear eosinophilic inclusion bodies mostly in oligodendrocytes. Electron microscopy showed intranuclear tubular structures indistinguishable from paramyxovirus nucleocapsids (Figure).

Discussion

The clinical diagnosis of SSPE in this case was suggested by the history of slowly progressive symptoms with prominence of mental deterioration followed by involuntary movements and myoclonus before there was major loss of cortical function. The EEG with periodic complexes at 5–6 seconds superimposed upon a generalised abnormality supported this.

In contrast, a review of the 20 cases of IME so far reported shows that this condition often starts with unilateral seizures progressing to generalised seizures and hemiplegia; occasionally there may be myoclonic jerks, epilepsia partialis continua, and involuntary movements. The progression from somnolence to coma may be very rapid, with death in several cases as early as 2–8 weeks after onset of symptoms. Except for 3 patients who survived with neurological damage, all have died within 5 months of onset. The EEG usually has a generalised abnormality often with focal discharges.

The CSF in IME is usually normal although there may be a slight increase in protein and cell count. The pronounced increase in IgG in our case is typical of SSPE. High measles antibody titre occurs in serum and CSF in both conditions and the measles virus has now also been isolated from the brain in IME (Aicardi *et al.*, 1977). A high level of measles-specific IgM in the CSF has so far been recorded only in SSPE, and in our patient it was 1:12.

In a comparison of the pathological changes in SSPE and IME, several reports of the latter have drawn attention to a singular lack of perivascular cuffing by inflammatory cells. This has, however, been present in most cases. Inclusion bodies and astrocytic gliosis typical of SSPE are also almost always noted in IME although microglial proliferation is somewhat less constant. Thus there is not a clear histopathological distinction from SSPE and the differences observed may largely depend on the duration of the disease.

SSPE and IME may well represent opposite ends of a spectrum of disease induced by measles virus persisting in the brain, and the nature and severity of immunological deficiency at the time of the initial infection may determine the latent period and rate of progress of the encephalitis. Various immunological abnormalities have been found in patients with SSPE (Addy, 1977) but proof that they were present when primary infection occurred and predisposed to the 'slow' virus infection is lacking. Our patient contracted measles when there were good reasons to suspect that cell-mediated immunity was still depressed: the exanthem appeared 3–4 weeks after cyclophosphamide treatment had been stopped because of neutropenia, and the girl received radiotherapy which has been shown to prolong drug-induced immunosuppression (Campbell *et al.*, 1973). Typical SSPE began 8 years later.

The only similar recorded case was that of Loirat *et al.* (1971); during immunosuppressive treatment for the nephrotic syndrome, this boy developed an exanthema suggestive of measles and he died 2 years later of an SSPE-like illness during which the serum measles antibody rose to a high titre. Necropsy was not performed.

We thank Dr E. McKay for his comments and permission to report details of the patient under his care, and Dr A. W. Downie for advice.

Response of neonatal hypocalcaemia to 1α-hydroxyvitamin D3

Y. BARAK, B. MILBAUER, Y. WEISMAN, S. EDELSTEIN, AND Z. SPIRER

Division of Paediatrics, and the Vitamins Research Laboratory, Municipal Governmental Medical Centre, Tel Aviv

SUMMARY Administration of 1α-OH-D3 to hypocalcaemic neonates (mean ±SD, serum calcium 1·50 ± 0·13 mmol/l) significantly increased serum calcium in all 24 infants within 48 hours after starting therapy (mean ±SD 1·83 ± 0·23 mmol/l). The time required to correct hypocalcaemia was significantly shorter (2·04 ± 0·56 days) in infants treated with 1α-OH-D3, than in 24 infants treated with calcium gluconate infusions (4·12 ± 1·0 days). Treatment with 1α-OH-D3 was effective, easy to maintain, and produced no side effects.

Decreased parathyroid hormone (PTH) secretion and/or end organ response, increased serum calcitonin concentrations, and defects in vitamin D metabolism have been implicated in the pathogenesis of neonatal hypocalcaemia (Tsang *et al.*, 1976). 1α,25-Dihydroxyvitamin D (1α,25(OH)$_2$D), the biologically active metabolite of vitamin D, which stimulates intestinal calcium transport, is synthesised by successive hydroxylation of vitamin D in the liver and kidney (DeLuca, 1976). Derangements in these metabolic pathways, and maternal vitamin D deficiency during pregnancy, may well be important factors in the pathogenesis of neonatal hypocalcaemia (Hillman and Haddad, 1975; Weisman *et al.*, 1976; Hillman *et al.*, 1977). We, therefore, investigated the effect of 1α-hydroxyvitamin D3 (1α-OH-D3), a readily synthesised and commercially available analogue of 1α,25(OH)$_2$D$_3$, in the treatment of neonatal hypocalcaemia.

Patients and methods

48 infants (mean gestational age 33·5 ± 2·8, ±SD

weeks; mean weight 1947 ± 613g, ±SD) with symptomatic hypocalcaemia presenting within the first 4 days of life were studied, with the informed consent of the parents. Most infants had muscular twitchings or apnoeic episodes and a few had frank convulsions. The serum calcium of each infant averaged <1·75 mmol/l (7 mg/100 ml). The radioassayable serum 25-hydroxyvitamin D concentrations were >25·0 nmol/l (≃10 ng/ml) in all patients (mean ±SD 58·0 ± 22·9 nmol/l (23·2 ± 9·1 ng/ml). All the patients received brief IV infusions of calcium gluconate to alleviate symptoms and were then divided randomly into two groups equally matched in gestational age and 1-minute Apgar score. Group 1 received 1α-OH-D3, 0·33 μg in arachis oil orally, twice daily for 5 days. Group 2 received IV infusions of calcium, 20 mg/kg per day, as 10% calcium gluconate. Serum calcium was determined twice daily by Eppendorf flame photometer.

Results

Administration of 1α-OH-D3 significantly increased serum calcium in each patient within 48 hours after starting treatment (Table) and there was no recurrence of the symptoms of hypocalcaemia. The mean recovery time (time required to correct hypocalcaemia) was significantly ($P<0·01$, *t* test) shorter in infants treated with 1α-OH-D3 (group 1) than in infants treated with calcium gluconate infusions (group 2). No episodes of hypercalcaemia were recorded. All infants remained normocalcaemic when 1α-OH-D3 was stopped.

Conversion SI to traditional units: Calcium—1 mmol/l ≈ 4 mg/100 ml.

Discussion

Renal 25-hydroxyvitamin D-1α hydroxylase activity is influenced by a variety of factors including serum and tissue concentrations of calcium, PTH, 25(OH)D, and $1\alpha,25(OH)_2D$ (DeLuca, 1976). Thus, impairment in the synthesis of $1\alpha,25(OH)_2D$ may be the end result of the derangements in PTH, calcitonin, and vitamin D metabolism, which have been implicated in the pathogenesis of neonatal hypocalcaemia (Tsang *et al.*, 1976; Weisman *et al.*, 1976). Indeed, newborn rats are unable to synthesise 1α,25(OH)D3 to detectable levels (Weisman *et al.*, 1976). The present data demonstrate the effectiveness of 1α-OH-D3 in the treatment of neonatal hypocalcaemia and are in good agreement with those of earlier studies in which $1\alpha,25(OH)_2D_3$ was evaluated for the prevention (Chan *et al.*, 1978), and treatment (Kooh *et al.*, 1976), of neonatal hypocalcaemia, and with one case report in which 1α-OH-D3 was given to an infant with protracted hypocalcaemia (Doxiadis and Lapatsanis, 1977).

1α-OH-D3 is converted to $1\alpha,25(OH)_2D_3$ *in vivo*, a necessary step for its biological activity (DeLuca, 1976). It was suggested that the hydroxylation of vitamin D to 25-hydroxyvitamin D may be impaired in premature infants (Hillman and Haddad, 1975). In our study, however, premature infants responded to treatment with 1α-OH-D3, indicating that 25-hydroxylation of 1α-OH-D3 had taken place in these infants. Traditional treatment of neonatal hypocalcaemia with continuous calcium gluconate infusions is difficult to maintain and may cause severe complications (Tsang *et al.*, 1976). However, 1α-OH-D3 treatment was easy to maintain and produced no side effects.

Acute intermittent porphyria and epilepsy

R. BIAGINI, R. TIGNANI, A. R. FIFI, AND L. NAPPINI

Divisione Pediatria, Ente Ospedaliero di Arezzo, Italy

SUMMARY A 14-year-old boy had suffered from intermittent acute hepatic porphyria, myoclonic convulsions, and mental retardation (Lennox-Gastaut syndrome). The porphyria was treated by stopping the administration of phenobarbitone and phenytoin. Sodium valproate at a dose of 70 mg/kg per day lessened the severity and frequency of convulsive crises.

Acute intermittent porphyria (AIP) is rare in children, but is not unknown. In a survey of reports on such children, Barclay (1974) found 37 cases but these were not all fully documented. In our opinion the age of the patient is of particular interest as is the association of AIP with epilepsy. The only 4 cases of hepatic metabolic disorder of porphyrins to have been fully described in infants associated with epilepsy are 3 of hereditary coproporphyria (Birchfield and Cowger, 1966; Haeger-Aronsen *et al.*, 1968; Houston *et al.*, 1977) and one of hepatic porphyria not better identified (Houston *et al.*, 1977).

Case report

A 14-year-old boy (born 4.12.1963) was the second child in an otherwise apparently healthy family with two other children. However, when examined his 39-year-old mother was found to have latent AIP.

During early infancy our patient had been moderately retarded in his psychomotor development, especially walking and speech. At 3 years he had generalised convulsions; during the clonic phase these mainly affected the right side. He was put on a course of phenobarbitone and phenytoin, or one of these, and although this treatment was changed and reassessed periodically, his condition did not improve. The length and frequency of the attacks increased and there was concurrent and progressive slowing down of his psychomotor development and learning ability, until at age 5, his IQ was 75. Because of his mental retardation and the fact that his repeated convulsive crises did not respond to drugs, he was sent to an institution and by age 11 his IQ was at a 5-year level.

Before coming to our attention, this child had three times been admitted to surgical departments with acute abdominal symptoms and constipation.

At age 13 he was admitted to a medical department with bronchopneumonia and underwent haemodialysis for anuria. Then, for the first time, in addition to the generalised convulsions, petit mal crises of variable length were recorded. The first was noted on the 14th day after admission. From the EEG findings, the neuropsychiatrist interpreted the neurological symptoms as Lennox-Gastaut syndrome. When the anuria ceased, despite the fact that the boy's urine was dark brown, no further diagnosis of AIP was registered.

We first saw this child in 1977 when he was aged 14. He had been admitted for clinical observation because of renewed episodes of abdominal pains and constipation. At that time there was a clinical picture of an acute attack of AIP.

We stopped those drugs which are now known to provoke acute crises of AIP and were able to reduce the number of seizures and ameliorate the acute clinical symptoms. By giving him sodium valproate *alone* (70 mg/kg per day) we have been able to reduce the frequency, duration, and gravity of the fits. With this diminution of fits and, subsequently, almost complete elimination of such crises, the patient's mental condition has improved.

Table 1 *Urinary porphyrins and precursors and uroporphyrinogen–1–synthetase enzyme activities in erythrocytes*

	Urinary porphyrins and precursors				*Uroporphyrinogen–1–synthetase enzyme activities in erythrocytes*		
	Age (*years*)	*Date*	*ALA* (*mg/24h*)	*PBG* (*µg/24h*)	*URO* (*µg/24h*)	*COPRO* (*µg/24h*)	*pmol/mg URO per mg protein per hour*

COPRO = coproporphirins normal: male 130–248 µg/24h. female 92–176 µg/24h. Uroporphyrinogen-1-synthetase enzyme activities in erythrocytes, normal 220–380 pmol/mg URO per mg protein per hour.

Table 2 *Seizure types and EEG patterns in our patient and in reports of 3 other children with hepatic symptomatic porphyria*

Case	*Year*	*Age at onset (years)*	*Type of porphyria*	*Seizure types*	*EEG*	*No. of antiepileptic drugs used*	*Mental state*
Present	1979	3	Acute intermittent porphyria	Falls, myoclonic tonic, clonic, atypical absences, hemiconvulsions, absence status	Slow spike wave	3	Severe mental handicap at age 14
Houston *et al.*	1977	2½	Hereditary coproporphyria	Falls, myoclonic tonic, atypical absences, clonic and hemiconvulsions	Slow spike wave, fast spiking in seizures	14	Hyperkinetic severe mental handicap at age 10
Haeger-Aronsen *et al.*	1968	10	Hereditary coproporphyria	Tonic, clonic with left clonic	'Partially paroxysmal'	1	Normal at age 13
Birchfield and Cowger	1966	3½	Hereditary coproporphyria	Febrile grand mal, 'akinetic', myoclonic, 'minor motor', atypical absences	Spike and wave repetitive spikes in seizure	14	Dullish normal at age 7

Discussion

The following points are of interest. (1) The mental handicap in our patient was the same as that described in 3 of 5 other cases (Birchfield and Cowger, 1966; Houston *et al.*, 1977). (2) There is a continuous need to adjust the treatment. (3) The severity of the epilepsy was such that the paroxysmal activity was 2·5 Hz on the EEG, suggesting a seizure disorder such as the Lennox-Gastaut syndrome. The epilepsy was equal in severity to the other cases (Birchfield and Cowger, 1966; Houston *et al.*, 1977). (4) The symptoms became much less when barbiturates and phenytoin were stopped and sodium valproate given alone at a dose of 70 mg/kg per day.

We, therefore, believe that our case lends further support to the claim of Houston *et al.* (1977) that there is a correlation between epilepsy and acute porphyria. In fact, the failure to diagnose AIP early and the unsuccessful anticonvulsive therapy probably hastened the acute crises which were attributed to AIP only in retrospect.

Table 1 gives the amounts of urinary porphyrins and precursors and uroporphyrinogen-1-synthetase enzyme activities in erythrocytes found both in the patient and in the mother on which the diagnosis is based (using the method of Grandchamp *et al.*, 1976).

Table 2 gives the principal clinical findings in our patient and those previously reported.

We thank Professor E. Rocchi, Department of Therapeutic Medicine, Institute of Medical Clinics, Modena University, Italy, for carrying out the enzymatic erythrocite assays and the quantitative evaluations of urinary porphyria.

Munchausen syndrome by proxy in twins

DEBORAH A. LEE

Department of Paediatrics, Preston Hospital, North Shields

SUMMARY A family is described in which twin infants had repeated admissions for apparent haemoptysis. It was proved that the mother was simulating these episodes and she eventually injured one of the children with a pin. The mother has subsequently shown some evidence of a Munchausen tendency in herself.

The spectrum of child abuse is ever widening with the recognition of the more obscure types of injury. Meadow (1977) described a child whose symptoms were fabricated by her mother, causing numerous investigations. He called this Munchausen syndrome by proxy. A further family is described in which there were similar occurrences.

Case report

Twins, a boy and a girl, weighing 2·5 kg and 1·9 kg respectively were born at 36 weeks' gestation by spontaneous vertex delivery. There were no immediate problems at birth. The boy was allowed home with his mother after 5 days. The girl was kept in the special care nursery for 3 weeks during which time parental visiting, although encouraged, was infrequent.

Both parents, previously married, were known to the Social Services Department because each had had children who were suspected, but not proved, to have been nonaccidentally injured. These children are now in the custody of the other remarried partners.

During the first 4 months, despite intensive support, there were 5 admissions for relatively minor illnesses. Then, on consecutive evenings, both twins were admitted with a history of having vomited blood. No cause was found for this and they were subsequently discharged. The same evening the girl was readmitted and the boy the next night, again having vomited blood. On this occasion, blood-stained bibs were produced. Aspiration of stomach contents showed no evidence of blood and again no cause was found for the bleeding. The next day, while the mother was feeding the boy in hospital, she reported that he was again bleeding. Blood was present on his clothing and on the mother's nursing gown. Thorough examination showed no bleeding points on the child. Mother and baby were known to have different blood groups so the clothing was sent for forensic analysis. At this stage it was thought that the mother was probably simulating the bleeding by injuring herself, and this was confirmed at a much later date by the forensic tests. However, the twins were allowed home in the knowledge that the mother had 'an escape route' when under pressure. The next evening both twins were readmitted, again having vomited blood and no cause was found.

A few days later while the mother was momentarily alone with the twins, blood appeared on the girl's chin. A nurse heard the baby crying, immediately examined her, and found a small bleeding point on her lower lip. He also saw a nappy pin that was almost hidden in the mother's hand. The twins were wearing selfadhesive disposable nappies which did not require the use of pins. The mother subsequently admitted injuring her child with the pin, was charged with assault, and found guilty. She consistently denied falsifying any of the previous episodes. The children were then both placed in the care of the local authority.

Discussion

Although it was recognised from before birth that the twins were at risk of child abuse they appeared to thrive and develop normally. The repeated admissions were accepted as a means of helping the family, although during admissions the parents rarely visited, and there was always delay in discharging the twins. In retrospect, we suspect that the mother felt unable to cope with both twins from early in their life, but could not admit this to her cohabitee. She found a means of escape by injuring herself and gaining relief from the children without showing her inadequacy. We think she may have deceived her entire family as several members had been present in the room on occasions when the bleeding had occurred. Why she should eventually injure one of the children is open to speculation, particularly as she had no concept of different blood groups and was therefore unaware that her falsification could be proved.

This case report differs from those previously described in that the sole gain to the mother was of relief from the children. The mother showed no previous Munchausen tendency, but since the twins have been taken into care she has presented to her doctor with a history of haemoptysis and also with a bleeding lesion on her breast which was extremely slow to heal.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onwards all manuscripts submitted should accord with the new style.

Correspondence

Anaemia in childhood coeliac disease

Sir,

There is considerable variation in the reported incidence of anaemia in childhood coeliac disease (Hamilton *et al.*, 1969; Walker-Smith, 1975). Both iron and folic acid deficiency may be present, but how often is not certain, and the value of red cell folate as a screening test is controversial. With these problems in mind, we examined the records of 91 children aged 2 months to 9 years, who had coeliac disease confirmed by jejunal biopsy over a 10-year period (1966–76) at the Bristol Children's Hospital.

The Figure shows the haemoglobin levels of children with coeliac disease and indicates which of these children had normal and which had low red cell folate levels (normal range of haemoglobin, Lascari, 1973). 37% of children were anaemic at diagnosis. The incidence of anaemia will depend on the population and the definition of anaemia. The incidence varies from 19% (Walker-Smith, 1975) to 80% (Hamilton *et al.*, 1969). Our results show that the incidence of anaemia is affected by the age distribution of the children at diagnosis. Mean haemoglobin was lower, and incidence of anaemia much greater (16/23 compared with 18/68, $P = <0\cdot05$) in children of at least 2 years. The reason for this difference with age is not clear. The duration of the illness before diagnosis may be important because of the time needed to deplete body stores of iron before erythropoiesis is effected. The mean duration of symptoms was much longer (184·4 weeks compared with 16 weeks) in the older children.

Coeliac children, whether they are anaemic or not, are likely to have low serum iron levels at the time of diagnosis. 87% (40/46) serum iron estimations were <12 µmol/l (<67 µg/100 ml), and percentage saturation of transferrin was below 16% in 93% of estimations. Blood film examinations showed that all anaemic children had moderate or pronounced red cell hypochromia. There was little morphological evidence of megaloblastic change. Three older children, all with low red cell folate levels, had some macrocytic red cells but hypersegmented neutrophils were not seen. Half (9/18) of red cell folate estimations in anaemic children were normal. Red cell folate is a poor screening test for childhood coeliac disease because half (17/34) of the estimations were normal in coeliac children at diagnosis.

We thank Dr Mary Seacome for her help.

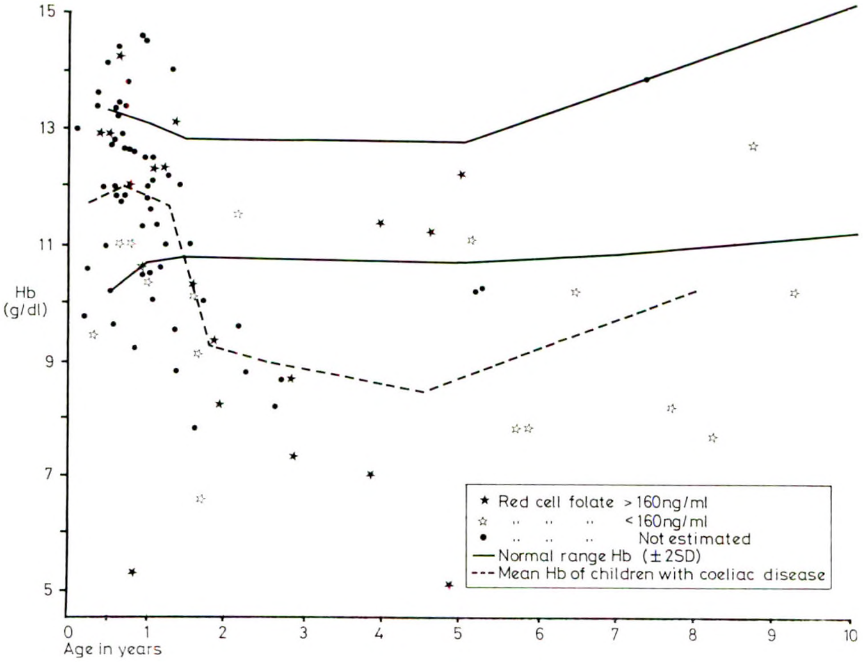

Figure *Haemoglobin levels in 91 children with coeliac disease.*

Coxsackievirus type A16 infection in a neonate

Sir,

Coxsackievirus type A16, commonly associated with the characteristic syndrome of hand, foot, and mouth disease, is an unusual infective agent in children under one year of age, particularly in the neonatal period. A short nonspecific illness in a newborn baby was shown to be associated with hand, foot, and mouth disease in his mother, and Coxsackievirus type A16 was recovered from both.

Case report

A 3-week-old baby boy was admitted with a 24-hour history of drowsiness and refusing feeds. Delivery had been normal at 35 weeks' gestation after premature rupture of membranes and intermittent labour pains for 10 days. Birthweight was 2·7 kg, and the baby had been nursed in the special care unit for 10 days because of a feeding problem associated with mild jaundice. Breast feeding had been maintained.

He was a well nourished but drowsy and slightly jaundiced infant: temperature 34·6°C; Dextrostix 25mg/100 ml. A full infection screen failed to show any focus of infection, and a provisional diagnosis of cold injury was made. It was found that his mother had been ill for 4 days previously, with a febrile 'flu-like' illness, associated with painful ulceration of her mouth, feet, and hands, Coincidentally with the infant's illness, a sibling also had nonspecific malaise.

Coxsackievirus type A16 was grown in monkey-kidney tissue cultures from maternal throat swab and vesicle fluid, and from the infant's throat swab; the infant's CSF was acellular and sterile.

The infant initially required tube feeding, and was nursed in an incubator until his temperature rose to normal. He was discharged home clinically well 5 days later.

Coxsackievirus type A16 infections are most commonly associated with hand, foot, and mouth disease, but have also been found in encephalitis, meningitis, myocarditis, and pericarditis. The highest incidence is in the 1- to 3-year-old age group (Gamble, 1962), and the incubation period is short, between 3 and 6 days. The disease is highly contagious, primary cases occurring in children, and spreading horizontally from sibling to sibling, and to parent.

The present case is interesting with regard to the age of the patient and the symptoms, which were relatively mild and atypical. Previously, neonatal infection with this agent has been reported in association with fatal myocarditis (Wright *et al.*, 1963; Golgberg and McAdam, 1965), but neonatal infections are rare, probably because of protection by maternal antibody (Gear, 1958; D. R. Gamble, 1977, personal communication). There are no previous reports of this infection being acquired postnatally from the mother. In this instance breast milk was not examined virologically, which might have shown the route of transmission.

Bronchodilator drugs and young children

Sir,

In their paper (*Archives*, 1978, **53,** 532), Lenney and Milner concluded that wheezy children under age 18 months did not respond to treatment with nebulised salbutamol, as measured by respiratory resistance or thoracic gas volume. They also quoted two other studies (Radford, 1975; Rutter *et al.*, 1975) which had similar conclusions. All these studies were performed in the recovery stage of an acute attack. In my experience, at the height of an attack, in the most severe stage, two-thirds of infants under one year show improvement in auscultatory findings when treated with nebulised salbutamol or isoetharine (König, 1978). Although no pulmonary function tests were done on infants of this age, there was a significant reduction in respiratory rate and dyspnoea score.

Although there is little doubt that the response of young infants to bronchodilators is less good than that of older children, I think that in the acute stage a substantial number of them do benefit and it is worth a trial.

USA

Dr Milner and co-workers comment:

We were interested to hear of Dr König's experience with nebulised salbutamol in children under one year. We accept that all our studies were carried out during the recovery phase but we have not found that any child under one year has obtained any useful, clinical benefit from nebulised salbutamol when administered in the acute phase. Since our paper was published, two children between the ages of 12 and 18 months have responded well, and we have since heard of another who apparently obtained benefit by age 11 months. We still recommend that salbutamol be given to all wheezing children over one year but think it unlikely that many children younger that this will respond to this form of treatment.

Intrathecal ATS and high dosage diazepam in neonatal tetanus

Sir,

We should like to make a few comments about the report by Khoo *et al.* (*Archives*, 1978, **53**, 737). Seven of the 19 neonates studied required total paralysis with IPPV for uncontrolled spasms, 2 died, and 5 more might have died but for total paralysis and IPPV. Therefore, it is not justified to say that improved survival was due to administration of high doses of diazepam alone.

Recently we initiated a study on the efficacy of a regimen consisting of intrathecal administration of antitetanus serum (ATS), and high doses of diazepam (15–30 mg/kg per day) and chlorpromazine (15–30 mg/kg per day) intravenously.

Between July and October 1978, we studied 10 neonates (Table). Diagnosis was on clinical grounds, and severity was graded using the criteria of Patel and Joag (1959). Immediately after admission an IV line was established and diazepam administered at the rate of 1 mg/kg per minute until the infant was free of spasm and rigidity. This was followed by administration of ATS, 250 IU intrathecally, and 1500 IU IV. Penicillin and gentamicin (5 mg/kg per day) were given. Infants were nursed in the paediatric ward. The umbilical cord was cleaned with spirit, and painted with gentian violet routinely. Pharyngeal suction was done at regular intervals.

Subsequent muscle relaxation was achieved by alternate IV administration of 2·5–7·5 mg diazepam and chlorpromazine, each at 2–4 hourly intervals (total daily dose of each drug 15–30 mg/kg). Once spasms had been controlled, a nasogastric tube was inserted for feeding and giving diazepam and chlorpromazine. Sedation was gradually tapered off at a rate of 10–15% of total dose administered at intervals of 1–2 days, depending on the degree of hypertonia. None of the infants was given IPPV with total paralysis.

Eight neonates recovered completely and 2 died, one of fulminant bronchopneumonia and the other with aspirant pneumonia. The average duration in hospital for the survivors was 20 days, and the average period for IV diazepam and chlorpromazine 3·4 days. We observed that the shorter the interval between the onset of the tetanus neonatorum and the intrathecal ATS, the quicker

Table *The 10 neonates* studied*

Case	*Gestational weight (kg)*	*Age at onset (days)*	*Instrument for cord cutting*	*Grade*	*Spasm controlled (hours)*	*Duration of sedation (days)*	*Hospital (days)*	*Outcome*
1	2·8	6	Blade	V	48	20	30	Recovered
2	2·6	6	Blade	V	48	7	13	Recovered
3	2·7	5	Razor	V	9 days	25	25	Recovered
4	3·0	9	Scissors	IV	24	12	12	Recovered
5	2·0 36 weeks	5	Scissors	V	Not controlled	—	—	Died 50 hours after being admitted
6	2·4	7	—	V	36	9	10	Recovered
7	2·1	6	Kitchen knife	V	Not controlled	—	—	Died
8	2·8	7	—	V	72	19	20	Recovered
9	3·0	7	—	V	48	10	11	Recovered
10	2·7	6	Blade	V	120	30	40	Recovered

*All were term except for Cases 5 and 6.

was the control of spasm and the shorter the duration in hospital. Besides thrombophlebitis at the site of venepunctures (probably secondary to benzoic acid present in injectable diazepam) a common complication was apnoea, which responded to partial withdrawal of diazepam. At 3–4 months all 6 neonates who returned for follow-up were developmentally normal.

We feel a combination of high doses of diazepam and chlorpromazine with intrathecal ATS (given early after onset of tetanus) is effective in reducing mortality.

SUNIT SINGHI AND PRATIBHA SINGHI
Department of Paediatrics,
JLN Medical College,
Ajmer (Rajasthan) 305001,
India

Dr Khoo and co-workers comment:

We did not claim that the low mortality rate in our patients with neonatal tetanus was due to high dose diazepam alone. Other equally important therapeutic measures that contributed to the improved survival rate in our patients included good nursing care, tetanus antitoxins, antibiotics, nutritional support, and the judicious use of sedatives. In our study, the use of continuous high dose IV diazepam (20–40 mg/kg per day) certainly decreased the mortality rate and also the need for artificial ventilation from 77 to 37% (Khoo *et al.*, 1978).

The treatment regimen advocated by Singhi and Singhi is very similar to ours except for the use of intrathecal ATS and the very high dose of chlorpromazine. The role of intrathecal ATS in the management of neonatal tetanus is still controversial (Laurence, 1975). The reason for injecting ATS into the CSF is to neutralise the tetanus toxin that has penetrated the CNS but has not yet begun to act. Besides, ATS given via the IV route penetrates the blood/CNS barrier poorly, and the levels of antitoxin in the CSF are approximately 400 times less than in the blood (Patel *et al.*, 1963; Ildirim *et al.*, 1969). In 1917, Sherrington obtained good results from the use of intrathecal ATS in monkeys with tetanus. It was subsequently tried in man but eventually abandoned because of adverse reactions to the CNS and doubts about its efficacy (Dietrich, 1940; Pratt, 1945). However, recent reports of the use of intrathecal ATS in tetanus are encouraging (Ildirim, 1970; Sanders *et al.*, 1977; Salimpour, 1978). Ildirim (1970) treated 28 cases of neonatal tetanus with intrathecal ATS and prednisolone mixture and had a low mortality rate of 10·7%. In another clinical trial on 322 cases of adult-type tetanus, 200 units intrathecal ATS (horse) was found to be an effective adjuvant in reducing the mortality rate from 14·5 to 4·5% (Sanders *et al.*, 1977). No complication was encountered apart from occasional difficulty in giving ATS intrathecally, while remarkable relaxation was observed in the patients.

With the availability of human antitetanus serum, which is relatively free of allergic side effects and less irritating to the CNS, the prospects for intrathecal ATS (human) is promising, but needs further tests before it can be recommended.

Book reviews

Down's Syndrome. The Psychology of Mongolism. By David Gibson. (Pp. 366; illustrated + tables. £18.50, hardback.) Cambridge University Press: Cambridge. 1979.

This book is a superb review of past and present literature on Down's syndrome from both sides of the Atlantic. Each aspect of psychological development has its own chapter with evaluation at the end. A more concise summary of some chapters would have been helpful. The chapters on foundation of intelligence and language are particularly good. Important medical aspects which contribute to the psychological profile are given due prominence—for example, intermittent hearing loss and disproportionate delay of language development—treatment with thyroxine having no effect in those who are euthyroid.

Remediation programmes are discussed and the short-term gains compared with the few long-term results.

This book is strongly recommended to anybody who is interested in Down's syndrome.

GILLIAN BAIRD

Pediatric Bronchology. By Edgár Székely and Edit Farkas. (Pp. 628; illustrated + tables. £39.50, hardback.) University Park Press: Baltimore. 1979.

This massive book is based on the authors' experience and expertise in over 30 000 bronchoscopical and radiological examinations of the bronchial tree during a period of 20 years at the Public Children's Sanatorium, Budapest. By its very nature, therefore, this volume is authoritative and is a highly significant contribution to our knowledge in this field. The contents of the book are divided into three sections: a general introduction to the concepts of paediatric bronchology, a detailed discussion of congenital abnormalities and pathological entities affecting the bronchi, and an account of the contribution made by bronchial catheterisation. The chapters are well illustrated with good quality colour endobronchial photographs and well reproduced contrast bronchograms. There is an extensive bibliography and indexes to authors and subjects.

Paediatric bronchology is a highly specialised field and there can be few institutions that could rival the experience of the authors. This work therefore will be of the greatest interest to all those in this branch of paediatrics. It should be eagerly read and used as a book of reference by paediatricians interested in pulmonary diseases, and by all those in allied specialities involved with examination of the bronchial tree in infants and children. Undoubtedly paediatric radiologists will find much new information to assist their evaluation of bronchographical examinations.

The book is beautifully produced and bound. The scope of the contents reflects the interests of the authors so that the reader must not expect all tracheobronchial diseases to be covered. For example, burns of the tracheobronchial tract, an increasingly common occurrence in this country, are not mentioned. It is unfortunate that the English translation does not match the other qualities of the production. The text therefore is not uniformly clear and it is to be hoped that this will be improved in the next edition. The references are mainly to European Continental literature which poses considerable problems to the English reader if original articles are to be consulted.

GORDON H. BUSH

Surgery of the Neonate. By Arnold G. Coran, Douglas M. Behrendt, William H. Weintraube, and Denis C. Lee. (Pp. 272; illustrated + tables. $32.50, hardback.) Little, Brown: Boston. 1978.

This volume, in the very specialised field of surgery in children in early infancy, details the techniques used by a group paediatric surgeons in Ann Arb Michigan.

The text is clear, well produced, easy follow, and reasonably succinct. There a brief list of references, some *x*-ı plates, and black and white line drawin Most of the drawings are clear and w produced, but the quality of the rad graphs leaves much to be desired. T abdominal *x*-rays are adequate, but found the reproductions of the ch *x*-rays and cardiac angiograms disappoi ing and of little value.

Descriptions of individual diseases a forms of treatment are reasonably cle but inevitably in this type of book t amount of text does not allow detail discussion of the results of treatment, n does it give alternative approaches.

I do not think this book will have wide appeal in this country. The work the neonatal surgeon in general no long includes special areas—such as cardi surgery, this falling within the province the specialised departments.

I feel the book is too specialised for t general registrar in training, and ina equate for the specialist who will seek more comprehensive presentation and d cussion of alternative techniques a results.

P. B. DEVERA

Shorter notice

Aplastic Anaemia. Edited by C. G. Gear (Pp. 249; illustrated + tables. £12.5 hardback.) Bailliére Tindall. 1979.

Comprehensive coverage of a fashionab and fascinating topic. Strong on clinic features and the limited treatment ava able, but I should have liked more abo the pathophysiology of marrow failur A useful chapter about marrow failure childhood with comprehensive referenc up to 1978. Otherwise a book for t specialist and/or the enthusiast.

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Phadebas RAST®
In-vitro test for atopic allergy.

PEDIATRIC RESEARCH

Volume 12, No. 10 October 1978

Contents

The Relationship of Amniotic Membrane 11-Oxidoreductase Activity to Lung Maturation in the Human Fetus 957

A. K. Tanswell and B. T. Smith (Kingston, Ontario, Canada)

The findings demonstrate that in pregnancies where the fetus is destined to develop respiratory distress syndrome after delivery, the amniotic membranes are defective in their ability to produce cortisol, resulting in a possible reduction in the amount of cortisol available to the fetal lung during maturation *in utero*.

Cellular and Humoral Immunity in Cartilage-Hair Hypoplasia 961

M. Virolainen, E. Savilahti, I. Kaitila, and J. Perheentupa (Helsinki, Finland)

In an unselected series of 28 subjects with cartilage-hair hypoplasia, almost all subjects had subnormal responses in tests of cellular immunity, although most of them had no apparent unusual susceptibility to infections. This feature was a more constant feature of the syndrome than the hair abnormality.

Salivary Amylase in Cystic Fibrosis: A Marker of Disordered Autonomic Function 967

G. P. Davidson, A. Koheil, and G. G. Forstner (Toronto, Ontario, Canada)

To determine whether an increased salivary isoenzyme activity might be present in cystic fibrosis, these scientists examined total serum amylase and isoenzyme patterns from a series of patients, including cystic fibrosis (CF) patients with and without steatorrhea, patients with exocrine pancreatic insufficiency without CF (Shwachman's syndrome), and a control group who had neither CF nor pancreatic insufficiency.

The Effect of Racemic, D-Propranolol, L-Propranolol, and Practolol on the Response to Cold by the Newborn Rabbit 971

I. Dober, V. Jaszai, T. Heim, and R. D. G. Milner (Pecs, Hungary, Toronto, Canada, and Sheffield, England)

In this investigation the newborn rabbit has been used as a model to investigate the effects of propranolol, the isomers of propranolol, and practolol on the response to cold exposure.

Fetomaternal Potassium Relations in the Rat on the Twentieth Day of Gestation. II. Effects of Maternal Hypocalemia 977

A. G. Fantel (Seattle, Washington)

A study of potassium homeostatis during maternal hyypokalemia was undertaken in potassium-deficient rats on the 20th day of gestation.

Plasma 25-Hydroxyvitamin D in Familial Hypercholesterolemic Children Receiving Colestipol Resin 980

R. C. Tsang, M. S. Roginsky, M. J. Mellies, and C. J. Glueck (Cincinnati, Ohio)

The effects of colestipol, a new synthetic organic bile sequestrant polymer (U26-597A), on vitamin D metabolism have been assessed in children with familial hypercholesterolemia over a 2-year period.

Pulmonary Diffusing Capacity in Lambs During the Early Neonatal Period 983

J. M. Bissonnette, W. H. Drummond, W. K. Wickham, and J. Z. Cronan (Portland, Oregon)

When a rebreathing method to measure pulmonary diffusing capacity in neonatal lambs was employed, a significant increase in diffusing capacity was found to take place in the first day of life.

Distortions in Fetal Growth Standards 987

R. L. Naeye and J. B. Dixon (Hershey, Pennsylvania)

The findings of the present studies indicate that widely used fetal growth standards appear to include measurements from both growth-retarded neonates and from neonates older than their calculated gestational ages.

Maturation of *p*-Aminohippuric Acid Transport in the Developing Rabbit Kidney: Interrelationships of the Individual Components 992

B. R. Cole. J. T. Brocklebank, R. G. Capps, B. N. Murray, and A. M. Robson (St. Louis, Missouri)

This investigation was undertaken to examine systematically the contribution of the individual cellular mechanisms to the reduction on aryl acid excretion in the immature rabbit kidney with *p*-aminohippuric acid being used as the test aryl acid.

Abnormal Colonization of Neonates in an Intensive Care Unit: Means of Identifying Neonates at Risk of Infection 998

K. Sprunt, G. Leidy, and W. Redman (New York, New York)

Results of these studies indicate that serial throat cultures permit selection of the group of Intensive Care Unit neonates at greatest risk of infection and indicate the probable organism from which they are at risk.

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42,** 109; 1973, **48,** 751; 1978, **53,** 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1,** 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Diseases of the Small Intestine in Childhood – 2nd Edition
JOHN WALKER-SMITH

In this second edition, several chapters have largely been rewritten and all contain new information. This reflects the rapid expansion of knowledge and interest in this field of paediatrics. The text is well illustrated.

23 x 15cm 384 pages Illustrated 0 272 79533 X £18.50net (Cased)

Prevalence of Illness in Childhood
ROMA N. CHAMBERLAIN AND RUTH N. SIMPSON

Describes the illnesses, hospital experiences and social and environmental factors affecting the health during the three years from the end of their first week of life of the members of a cohort of 16,000 babies born during one week in England, Wales, Scotland and Northern Ireland. It will be of value to all concerned with the care of children and is of special importance to those concerned with the planning of child health services.

23 x 15cm 260 pages 0 272 79533 4 £10.00net approximate (Cased)

Placental Transfer
GEOFFREY CHAMBERLAIN AND ANDREW WILKINSON

Alterations in placental function may be followed by major changes in the state of the fetus. Until recently most tests of placental function have measured endocrine metabolism rather than the transfer capacity of the placenta, and the relationship between the two may be variable.

This book contains information about the transfer of many substances required by the fetus and shows the effects of diminished placental transfer in many species.

BRITISH COUNCIL MEDICAL COURSE

PAEDIATRIC GASTROENTEROLOGY

16 - 28 March 1980 in Birmingham

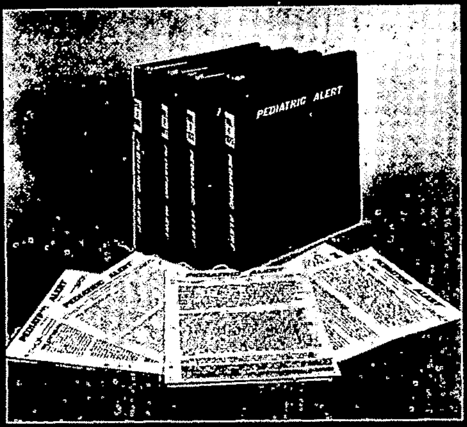
The Directors of Studies will be Professor Charlotte M Anderson, Professor of Paediatrics and Child Health, University of Birmingham and Professor A S McNeish, Professor of Child Health, University of Leicester School of Medicine. This course will deal with theoretical and practical aspects of Paediatric Gastroenterology, highlighting recent knowledge, and will include case presentations of particular interest. The course is for those who have a substantial clinical or research interest in paediatric gastroenterology. It will also be relevant to clinicians who have responsibility for establishing or developing paediatric gastroenterology, and to research workers whose major interest is in paediatric gastrointestinal pathophysiology in the broad sense.

There are vacancies for 35 members.

Fee including demi-pension accommodation £540.

Please apply by 15 October 1979.

Further information and application forms are available from local overseas Representatives of the British Council or from the Director, Courses Department, The British Council, 65 Davies Street, London W1Y 2AA, Britain.



Keep up . . . with *PEDIATRIC ALERT*®

THOUSANDS OF PEDIATRICIANS AROUND THE WORLD RELY ON *PEDIATRIC ALERT* TO KEEP THEM INFORMED ABOUT THE MOST CURRENT DEVELOPMENTS AFFECTING THE PRACTICE OF PEDIATRICS.

***PEDIATRIC ALERT* will promptly provide you:**

ABSTRACTS of important articles from the world's most current medical literature. Always concise and easily read.

- **REPORTS from medical meetings**
- **SUMMARIES of important news in the lay press**
- **COMMENTARIES by Editorial Advisory Board members and other authorities**
- **QUARTERLY SUPPLEMENTS that examine a single topic in depth**

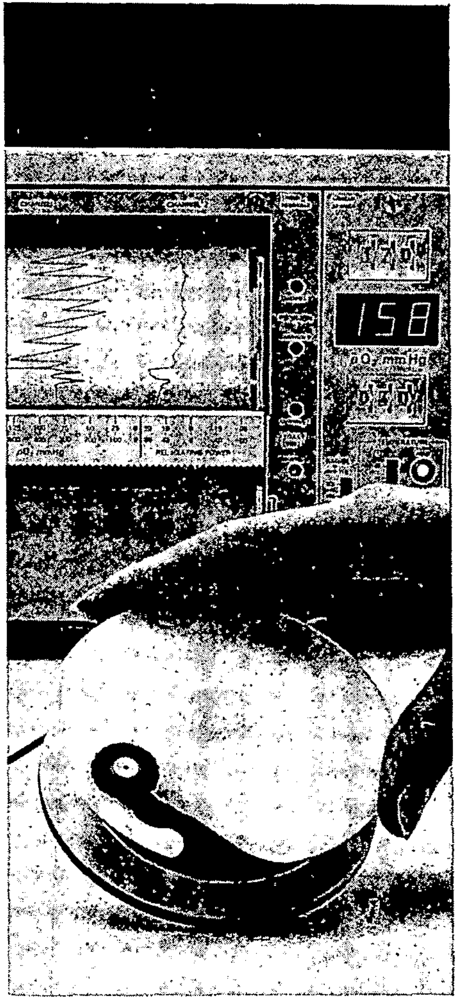
Taking blood oxygen measurement is as simple as this.

The Draeger
ymeter gives you
nplicity with precision.
The vital job of
aining blood oxygen
asurements is a
nple, straightforward
ocedure with the
aeger oxymeter.
It's entirely non-
asive and non-
umatic and there is no
k of blood infection or
ombosis.
It's simple. The
ctrode is attached to
e skin, a few minutes
owed for warm-up,
d the reading is
ailable.



It's precise.

Several published papers attest to this.

And it's stable. Precise measurement is maintained over long periods of use and response to pO_2 fluctuations is swift.

The Draeger oxymeter is a valuable aid in monitoring patients in neonatal and adult intensive care.

Its value will be more than apparent when you have read the literature and we'll be pleased to send you copies as soon as you ask.

Total parenteral nutrition in very low birthweight infants: a controlled trial

V. Y. H. YU, B. JAMES, P. HENDRY, AND R. A. MACMAHON

Department of Paediatrics, Queen Victoria Medical Centre, Melbourne, Australia

SUMMARY 34 preterm infants with birthweights <1200 g were randomly assigned to total parenteral nutrition (TPN) or oral (Milk) feeding regimens for the first 2 weeks after birth. Infants in the TPN group were started on a modified Vamin-based glucose amino-acid infusion and Intralipid. The daily amounts of carbohydrate, amino-acids, and fat infusions were increased. In the Milk group, infants were started on intermittent gavage feeding, supplemented with a glucose-electrolyte infusion as necessary. The overall mortality rate did not differ in the two groups. Four infants in the Milk group developed necrotising enterocolitis but none did in the TPN group. Despite mean daily energy intakes which were not greatly different, there were much higher mean daily intakes of carbohydrate and protein in the TPN group compared with the Milk group. Fat intake in the TPN group was lower than in the Milk group in the 1st week because of neonatal jaundice which contraindicated the use of Intralipid. There was no difference in the mean daily fat intake by the 2nd week. Although mean daily weight loss in the 1st week and the maximum postnatal weight loss in the two groups were similar, infants in the TPN group had a greater mean daily weight gain in the 2nd week and took less time to regain and maintain birthweight. Metabolic complications were equally common in both groups and were reversible with early recognition. Limits of tolerance for water and most nutrients tended to be variable and the nutritional programme had to be adjusted for each baby. Nevertheless, we found that TPN, when properly managed, is an effective and safe procedure in very low birthweight infants.

Advances in neonatal intensive care have resulted in better survival of very low birthweight infants. Adequate nutrition in the preterm neonate is considered to be important for immediate survival (Heird *et al.*, 1972b) and for subsequent normal growth and development (Dobbing, 1974). This need for nutritional support often leads to the overzealous early introduction and excessive increases in volume of milk feeding, with a resulting increased risk of aspiration pneumonia (Wharton and Bower, 1965), cardiorespiratory disturbances (Yu, 1976), or necrotising enterocolitis (Yu *et al.*, 1977).

Partial parenteral nutrition as a supplement to inadequate oral intake has been used successfully in low birthweight infants (Benda and Babson, 1971; Cashore *et al.*, 1975), although comparative studies of parenteral supplementation versus conventional feeding regimens showed similar morbidity and mortality (Bryan *et al.*, 1973; Pildes *et al.*, 1973; Brans *et al.*, 1974; Abitbol *et al.*, 1975). The feasibility of supplying complete requirements with total parenteral nutrition (TPN) via centrally placed catheters has been reported (Driscoll *et al.*, 1972; Peden and Karpel, 1972; MacMahon *et al.*, 1975; Hall and Rhodes, 1976; Meng *et al.*, 1977). Although most reports claimed benefits with these techniques all but one (Gunn *et al.*, 1978) lacked proper controls.

Because complications from intragastric milk feeding will contribute to the morbidity and mortality of very low birthweight infants, a study was accordingly designed to compare TPN with intragastric milk feeding supplemented as necessary with only a glucose-electrolyte solution.

Patients

Infants <1200 g birthweights born, at the Queen Victoria Medical Centre or referred within 24 hours

---

Department of Paediatrics, Queen Victoria Medical Centre, Melbourne
V. Y. H. YU, director of neonatal intensive care
B. JAMES, professional officer
P. HENDRY, technical officer
R. A. MACMAHON, associate professor

LIBRA

of birth, were considered for the study. After obtaining informed parental consent, the infants were assigned to a feeding regimen of either TPN or intragastric milk feeding (Milk). Assignment was by random card selection on alternate infants with the infant immediately following qualifying for the opposite study group. 40 infants <1200 g birthweights, admitted to the neonatal intensive care unit during the 12-month period between July 1977 and June 1978, were consecutively enrolled in the study with all babies complying. Six infants died within 24 hours after birth before starting TPN or Milk feeding and were excluded. Therefore, 34 infants were studied.

Methods

Milk group. Intermittent gavage feeding via an orogastric tube was started as soon after birth as the clinical condition of the baby allowed. This was usually begun on day 1 and given every hour using fresh expressed breast milk from the infant's own mother, or a 67 kcal (280 kJ)/100 ml milk formula (Similac, Ross Laboratories, N.S.W., Australia) if the former was unavailable.* The volume of milk was increased as rapidly as tolerated without abdominal distension, gastric retention, or regurgitation. An intake of 150 ml/kg per 24 hours was usually provided but this varied between 100 and 200 ml/kg, depending on the clinical condition of the infant. An infusion of dextrose, water, and electrolytes was supplemented as necessary to maintain normal hydration and biochemical status. The infusate consisted of 5% dextrose and this was increased to a 10% solution as tolerated. As the oral intake increased, so was the infusion rate decreased. Daily oral multivitamin supplements were given from the 1st week. Any infant in the Milk group who remained nil-orally for more than 3 days after birth or in whom feeds had to be withheld for more than 24 hours subsequently during the 2-week trial period was considered as a trial failure and withdrawn. The subsequent progress of such infants is excluded from the analysis of results. Trial failure infants and infants whose oral intake was <100 kcal/kg on day 14, on completion of the 2-week trial period, were offered parenteral nutrition supplements.

TPN group. A glucose amino-acid solution, based on Vamin N (Vitrum, Stockholm, Sweden) with added electrolytes, vitamins, and trace minerals was prepared by the pharmacy according to the programme shown in Table 1. TPN was prescribed on admission to the study beginning with formula 1A. The glucose infusion rate was increased from 8 to 18 g/kg per 24 hours in daily increments of 2 g/kg by upgrading from formula 1A to 3B if hyperglycaemia (blood glucose >11 mmol/l; >198 mg/100 ml) or glycosuria (Clinitest >0·5%) was not encountered. The programme allowed for an increase in the daily amount of amino-acid infused from 1 to 3 g/kg over 6 days. If there was glucose intolerance, the daily amount of glucose was adjusted, independent of the amino-acid intake. A soybean emulsion (Intralipid 20%, Vitrum, Stockholm, Sweden) was started at a level of 1 g/kg fat per 24 hours after recovery from neonatal jaundice (serum bilirubin <150 μmol/l (<8·8 mg/100 ml) and falling). This amount was increased, in the absence of visible lipaemia, to a maximum of 3 g/kg per 24 hours. If daily serum specimens showed more than a trace of lipaemia (equivalent to 2·8 mmol/l (250 mg/100 ml) triglyceride), lipid intake was reduced. The electrolyte content of the TPN solution was adjusted as shown by the biochemical status. As with infants in the Milk group, an intake of 150 ml/kg per 24 hours was generally provided, but this varied between 100 and 200 ml/kg depending on the clinical condition of the infant.

Infusion technique. TPN and supplemental glucose solutions (in the Milk group) were infused via the indwelling umbilical arterial catheter inserted in infants with respiratory distress or via peripheral veins when the former was not required. Catheter placement was in the descending aorta with the tip

*Similac has a composition close to that of human breast milk (protein 1·5 g/100 ml, fat 3·7 g/100 ml, carbohydrate 7·0 g/100 ml) prepared from nonfat cows' milk, vegetable oil, and added lactose.

at the level of the 3rd lumbar vertebra. An 0·22 μm Ivex 2 filter (Millipore, N.S.W., Australia) and an Ivac infusion pump (Watson-Victor, Victoria, Australia) were used for the glucose amino-acid infusion. Intralipid was infused continuously with a Harvard Syringe Pump (Stansen, Victoria, Australia) joining the glucose amino-acid mixture in a Y-connector distal to the filter and just proximal to the arterial catheter or intravenous needle. Infusates and administration sets were changed daily.

Monitoring. The infants were weighed daily to the nearest 10 g. Urine was analysed at least twice daily for osmolality and glucose. Serum osmolality, glucose, sodium, potassium, calcium, magnesium, chloride, phosphate, and bilirubin (total and direct); haemoglobin and haematocrit; and acid-base status were measured daily in the 1st week and on alternate days in the 2nd week of the study. The volume of blood required for these tests was 1·4 ml. The serum was also checked daily for visible lipaemia. Serum glutamic-oxalo-acetic transaminase, alkaline phosphatase, protein, urea, ammonia, lactate, transferrin, caeruloplasmin, and trace elements (Fe, Cu, Zn, Mn, Cr) were measured on days 7 and 14 of the study. The volume of blood required for these tests was 1·7 ml. Urine collection for 24 to 72 hours was done during the period of a nitrogen balance test.

Statistical evaluation. Significance of differences between fluid and nutrient intakes and body weight changes in infants on the two feeding regimens was determined using the Mann-Whitney U test.

Results

Clinical data and mortality. No significant difference in birthweights or gestational ages was noted between the 34 infants in the study and the 6 infants who died within 24 hours after birth (Table 2). Overall mortality for infants <1200 g was 32·5%. Seven of the 34 infants in the trial died (mortality rate 20·6%), 5 during the 2-week trial period and 2 in the 3rd week after birth.

The clinical data of the 17 infant pairs are summarised in Table 3. The groups were comparable in regard to birthweight and gestation. No infant had a birthweight under the 10th centile for gestational age. There were more boys, more infants with respiratory distress or apnoea, and more babies requiring oxygen or assisted ventilation in the TPN group compared with the Milk group. The differences were however, not significant. The mortality within the trial period in the TPN group (3 or 18%) was not statistically different from that in the Milk group (2 or 12%).

Four infants in the TPN group failed the trial. In one infant, the glucose amino-acid solution was not started within 3 days of birth because of severe metabolic acidosis from group B β-haemolytic streptococcal pneumonia. She subsequently recovered with treatment. The remaining 3 infants died during the course of the trial; 2 had intraventricular haemorrhages, one on day 3 and the other on day 5, and one baby had a pulmonary haemorrhage on day 14. A further infant in the TPN group died after the trial, on day 21, from an intraventricular haemorrhage.

Six infants in the Milk group failed the trial. One died on day 2 of an intraventricular haemorrhage and one died on day 14 as a result of necrotising enterocolitis. Three other infants developed necrotising enterocolitis on days 8, 10, and 12, all of whom recovered with treatment. One infant had aspiration pneumonia on day 14. A further infant in the Milk group died after the trial on day 19 of an intraventricular haemorrhage. Trial failures in the two groups are summarised in Table 4.

Intake. Data on volume and energy intake are shown in Table 5. The mean daily volume intake during the 1st week was 152 ml/kg per 24 hours in

both groups. In the 2nd week, infants in the Milk group required significantly higher daily mean volume intakes compared with those in the TPN group in order to maintain normal hydration and serum osmolality. Milk provided an average of 62% of the volume intake on day 7 and 83% by day 14 (Fig. 1). With the exception of 3 infants who were fed exclusively on Similac and one infant who died before starting milk feeds, the remaining 13 infants in the Milk group were given fresh expressed breast milk, even though this was often complemented with Similac when the supply of breast milk was interrupted.

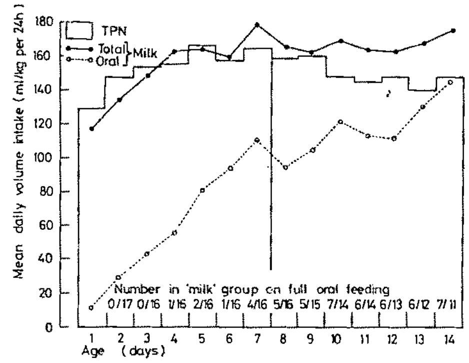

Fig. 1 *Comparison of volume intake in the TPN and Milk groups.*

The mean daily energy intake in the 1st and 2nd week was not significantly different in the two groups (Table 5). The number of infants and the ages at which they attained the desired energy intakes according to data of Cashore *et al.* (1975) were determined. 14 infants in the TPN group attained the parenteral desired energy of 90 kcal (380 kJ)/kg per 24 hours during the study period at an average age of 7 days compared with 7 infants in the Milk group who attained the oral desired energy intake of 120 kcal (500 kJ)/kg per 24 hours at an average age of 11 days. This difference was statistically significant. Milk provided an average of 78% of the energy intake on day 7 and 93% by day 14 (Fig. 2).

The mean daily carbohydrate, protein, and fat intakes in the two groups during the 1st and 2nd weeks are shown in Figs 3 and 4. There was a significantly higher intake of carbohydrates and protein in both weeks in the TPN group compared with the Milk group. 14 infants in the TPN group attained the desired protein intake of 2·6 g/kg per 24 hours during

the study period compared with 9 infants in the Milk group. Mean daily fat intake during the 1st week was significantly lower in the TPN group compared with the Milk group. With infants in the TPN group, Intralipid was started only after recovery from neonatal jaundice at a mean of 7 days with a range of 5 to 11 days. No significant difference was observed in the mean daily fat intake in the 2nd week.

Weight changes. Table 6 and Fig. 5 show the weight changes for the two groups. There was no statistical difference in the mean daily weight loss in the 1st week and the maximum postnatal weight loss in the two groups. Infants in the TPN group began to gain weight sooner and faster compared with those in the Milk group, as shown by a significantly earlier age at lowest weight, a greater mean daily weight gain in the 2nd week, and a shorter mean time to regain and maintain birthweight. There was no statistical difference between the two groups in the age at which the infants attained 2000 g or the time of discharge from hospital. However, 3 of the 10 infants in the Milk group whose oral intake was still under 100 kcal/kg at the end of the 2-week trial were offered parenteral nutrition supplements, and 5 of the 27 survivors were transferred to the referring hospital for convalescent care before discharge. Such comparisons beyond the trial period are therefore difficult to interpret.

Complications. Metabolic disturbances are summarised in Table 7. Serum hyperosmolality was detected in 4 infants in the TPN group and in 2 in the Milk group. None of these infants developed intracranial haemorrhage. Hyperglycaemia was observed in both groups. All responded promptly to appropriate adjustments in the glucose infusion rate and insulin was not required. Electrolyte

Conversion: SI to traditional units—glucose: 1 mmol/l ≈ 18 mg/100 ml; calcium: 1 mmol/l ≈ 4 mg/100 ml; magnesium: 1 mmol/l ≈ 2·4 mg/100 ml; lactate: 1 mmol/l ≈ 9 mg/100 ml; bilirubin: 1 μmol/l ≈ 0·06 mg/100 ml; urea: 1 mmol/l ≈ 6 mg/100 ml.

disturbances were comparable in both groups and were corrected as they appeared. TPN did not contribute significantly to the severity of metabolic acidosis compared with the conventional feeding method. Most infants in both groups developed hyperbilirubinaemia >150 mmol/l and required phototherapy. An increase in conjugated bilirubin was observed in 3 infants in the TPN group who also had raised AST levels at the end of TPN. One had cholestatic jaundice associated with postnatally acquired cytomegalovirus infection. There was a transient increase in the level of blood urea in one infant in the TPN group, and one infant in the milk group had one reading of a high blood ammonia level.

Bacterial or fungal septicaemia was not a complication in infants in either group during the study period. One infant in the TPN group who continued to require TPN for 10 weeks subsequently developed candida septicaemia but recovered on systemic amphotericin B.

Discussion

Results are given of a controlled study of 34 critically ill low birthweight infants, half of whom received intragastric milk feeding and, as necessary, IV glucose and electrolyte supplements. The other half received total parenteral nutrition. As the conventional practice is to establish an intra-arterial infusion on admission, infants in the Milk group all had IV glucose which supplemented the fluid and energy intakes during the period in which the volume of milk feeds was increased. It is therefore not possible to obtain a 'pure' milk feed group in infants under 1200 g. However it was considered that a true assessment of the advantages of parenteral nutrition for such infants could be gained only if the latter replaced milk feeding rather than supplemented it. Interpretation of previous reports of total parenteral nutrition is difficult in the absence of adequate controls fed conventionally under identical medical supervision. Studies have been biased by excluding infants with respiratory distress or those who required assisted ventilation (Driscoll *et al.*, 1972; Bryan *et al.*, 1973). Yet, these are the very infants who would particularly benefit from more calories and who are most difficult to feed orally. In the present study, infants were randomly assigned to a feeding method and none was excluded after starting the designated regimen.

Dweck and Cassady (1974) reported that hyperglycaemia was observed in 86% of very low birthweight infants receiving parenteral glucose. This was reported to be related to high glucose infusion rates exceeding 9·6 g/kg per 24 hours. Accordingly, the TPN regimen was designed to begin with a glucose load of 8 g/kg per 24 hours on day 1. It was possible, however, progressively to increase the mean glucose infusion rate within tolerance limits to 18 g/kg per 24 hours by 7 days after birth. The incidence of hyperglycaemia in the TPN group was similar to that in the Milk group. This complication was resolved by lowering the glucose infusion rate.

Formulated crystalline amino-acid mixtures are more effective than protein hydrolysates as the latter contain considerable amounts of small peptides that are not efficiently used. Of the crystalline amino-acid solutions, Vamin contains only L amino-acid isomers and is more efficiently used with respect to nitrogen metabolism than that containing both the D and L isomers, as in the case of Aminofusin (Pfimmer, Erlangen, West Germany), because of lower urinary amino-acid losses (Hendry *et al.*, 1978). Furthermore, Vamin maintains serum amino-acid concentrations that are close to normal in small premature infants (Shaw *et al.*, 1977), whereas Aminofusin seriously disrupts normal amino-acid concentrations (Kellerman *et al.*, 1976). The recommended dose of 3 g of amino-acids (equivalent approximately to 2·6 g protein)/kg per 24 hours given in this study, using Vamin as the nitrogen source, is based on work previously carried out here (Kellerman *et al.*, 1976; Shaw *et al.*, 1977; Hendry *et al.*, 1978). Heird *et al.* (1972a) suggested that the metabolism of excessive cationic amino-acids results in excess of hydrogen ion which leads to metabolic acidosis during parenteral nutrition. The incidence of this complication was low and similar in the TPN and Milk groups. It is possible that the acetate in the TPN solution acts as a bicarbonate precursor and is capable of buffering the excess hydrogen ion formed. Hyperammonaemia observed in infants given parenteral nutrition has been attributed to high ammonia content in protein hydrolysates or to inadequate arginine in the crystalline amino-acid solution (Heird *et al.*, 1972c; Johnson *et al.*, 1972). This complication was not observed in this study.

Less mature infants had a poorer Intralipid tolerance initially, as was observed by Shennan *et al.* (1977). However, most infants tolerated 3 g/kg fat per 24 hours by the 2nd week as had been shown previously (Cashore *et al.*, 1975; Gunn *et al.*, 1978). It has been noted, however, that some infants on Intralipid can develop high plasma levels of free fatty acids which can interfere with bilirubin-albumin binding and thus increase the risk of bilirubin encephalopathy (Andrew *et al.*, 1976). As we had no method for monitoring the effects of free fatty acids on bilirubin-albumin binding, it was decided that an increasing serum bilirubin level, or one >150 μmol/l, is a contraindication for Intralipid. This was found to occur in all the infants in this series within the first 5 days, thus contributing to the insufficient energy intake in the TPN group during this early period. Adequate monitoring of the Intralipid-bilirubin relationship by determining the reserve bilirubin-binding capacity or by calculating the free fatty acids to albumin molar ratio will provide a safety index for Intralipid use in the presence of neonatal jaundice.

The introduction of neonatal intensive care has led to a decrease in the mortality rate of very low birthweight infants (Stewart *et al.*, 1977). At the Queen Victoria Medical Centre, infants weighing <1000 g had over 80% mortality in the 3 years 1970 to 1972 (MacMahon *et al.*, 1975), whereas the mortality rates for those weighing 501 to 1000 g and 1001 to 1500 g were 52 and 20% respectively during 1977 (Yu and Wood, 1978). The reason for this improvement in outlook is obviously multifactorial, of which early adequate nutrition provided by safer methods is only one factor. An effect upon mortality can only be formally demonstrated by a carefully controlled study. However, it is impossible to isolate this one factor in the very low birthweight infant in whom the mortality will, in any case, be high. As in the one previous report of TPN versus a control group managed with the conventional feeding regimen (Gunn *et al.*, 1978), no statistically significant differences in mortality rate between the two groups could be shown. One factor which is not comparably matched in the two groups is the sex of the infants. The fact that there were 10 girls in the Milk group compared with 6 in the TPN group suggests that the Milk group was more favourably placed, allowing for the expected male preponderance in mortality.

Infants in the TPN group had earlier and greater weight gain than those in the Milk group, despite similar total caloric intake. Oral nutrients are poorly absorbed in preterm infants. The energy need in achieving weight gain observed in the present study is in agreement with that by Cashore *et al.* (1975) who reported that most infants gained weight at the expected rate of fetal growth *in utero* (20 g per day at 28 weeks and 30 g per day at 34 weeks) when the desired energy intake of 90 kcal(380 kJ)/kg per 24 hours of parenteral nutrition or 120 kcal(500 kJ)/kg per 24 hours of milk feeding was attained. Furthermore, the nitrogen intake of the Milk group was significantly lower than that of the TPN group for the duration of the study. In the 2nd week, the TPN group achieved the recommended parenteral nitrogen requirement of Vamin-fed preterm infants (Hendry *et al.*, 1978) of 30 mmol/kg nitrogen per 24 hours, equivalent to 3·1 g of amino-acids or 2·6 g/kg protein per 24 hours. The latter study also showed that only 80% of the oral nitrogen intake in these Similac-fed infants was absorbed, which put the infants in the Milk group at a further disadvantage. It has nevertheless been suggested that the faster weight gain observed in parenterally supplemented infants compared with their orally-fed controls might be attributable to water retention rather than to more rapid tissue accretion (Brans *et al.*, 1976); but in that study, there was no difference in daily protein intake between the two groups. Firm conclusions must await further studies, including concomitant estimates of total and extracellular body water.

Comparison of the morbidity in the two groups showed that no baby in the TPN group had necrotising enterocolitis whereas 4 infants in the Milk group developed this during the first 2 weeks, one of whom died despite surgical intervention for intestinal perforation. Enteric feeding, particularly for babies with mucosal ischaemia, was thought to be of aetiological significance in the development of necrotising enterocolitis (Yu and Tudehope, 1977). This has to be considered as a significant morbidity associated with milk feeding in very low birthweight infants in addition to the more commonly described aspiration pneumonia for which there was also one example in the Milk group in the present study. The incidence of intraventricular haemorrhage was similar in the two groups. None of the 5 infants with this complication had serum hyperosmolality but 4 of them, 2 in each group, had blood glucose levels >11 mmol/l. A further 11 infants were found to have transient hyperglycaemia but did not develop intraventricular haemorrhage. Though TPN in this study has not been shown to increase the incidence of hyperosmolality or hyperglycaemia compared with milk feeding, the clinical implication of hyperglycaemia in intraventricular haemorrhage (Dweck and Cassady, 1974) needs further study.

Metabolic complications were relatively common, but in no case were these persistent or considered to have resulted in serious consequences. The number of recorded disturbances could be attributed to the fact that the infants were closely monitored. Constant laboratory support, using microtechniques, was needed for early diagnosis so that rapid adjustments in the composition of the infusate could be made. However, it is reasonably certain that if monitoring had been less thorough or if a 'standard' mixture had been used, serious and perhaps fatal metabolic complications could have ensued.

This controlled study has shown a more adequate nitrogen intake and an improved weight gain, an avoidance of necrotising enterocolitis, but an unchanged mortality rate in very low birthweight infants managed with TPN compared with conventional milk feeding during the first 2 weeks after birth. Complications which could be specifically assigned to TPN were few. The possibility that TPN may be responsible for intrahepatic cholestasis in some very low birthweight infants is being investigated. Long-term studies of neurological, intellectual, and behavioural development are needed and are currently in progress.

We thank Dr M. Adamson, Dr P. Das, Dr B. Jack, and Dr T. Lambert, consultants in the Neonatal Intensive Care Unit, Miss E. Hollingsworth (charge sister) and her nursing staff, Mr R. Arulappu (Director of Pharmaceutical Services) and his staff, and the Biochemistry Department of the Medical Centre for their co-operation in the study.

This project was supported in part by NH and MRC grant number 69/5038.

Numerical evaluation of facial pattern in children with isolated pulmonary stenosis

HOWARD AINSWORTH, JAMES HUNT, AND MICHAEL JOSEPH

Evelina Children's Department, Guy's Hospital Medical School, and the Department of Paediatrics, Cardiothoracic Institute, London

SUMMARY A facial contouring technique, using light sectioning (Cobb, 1972), was modified (Ainsworth and Joseph, 1977) and used in a numerical study of children with isolated pulmonary stenosis (PS) to test the hypothesis that the facial pattern in this condition differs from the normal. Measurements were compared between a group of 20 normal children and a group of 20 children with PS between ages 6 and 10½ years. A distinctive facial pattern emerged. Many anteroposterior measurements were much greater in the PS group, indicating that the tissues were more prominent in the maxillary region. Altogether, 29 measurements showed significant differences ($P < 0 \cdot 05$) between the two groups. Discriminant analyses were carried out to discover which, if any, might be used to predict the group to which an individual should belong. Depending on the variables chosen, between 34 and 37 individuals from the total of 40 were assigned to the correct group—PS or control.

Detailed measurements of facial abnormalities in the child have not been made. A general subjective approach has usually been used which relies on the experience of the observer. The lack of suitable measuring techniques has been responsible for this approach.

Facial patterns are common in some congenital heart diseases, notably supravalvar aortic stenosis (Joseph *et al.*, 1966) and the cardiofacial syndrome (Cayler, 1969; Chantler and McEnery, 1971). It has been suggested that children with isolated pulmonary stenosis (PS) have moon faces (Wood, 1950), and Nadas (1963) referred to their round faces and broad cheeks. We too had a strong impression that patients with PS had a recognisable pattern and we wished to test this hypothesis by carrying out a detailed numerical analysis. An example of the facies in a child with PS is shown in Fig. 1.

The methods of moire fringe contouring (Takasaki, 1970) and stereophotogrammetry (Ainsworth and Joseph, 1976) were considered but finally a light-sectioning device (Cobb, 1972) which produced facial contour maps was chosen. It was used after modifications had been made.

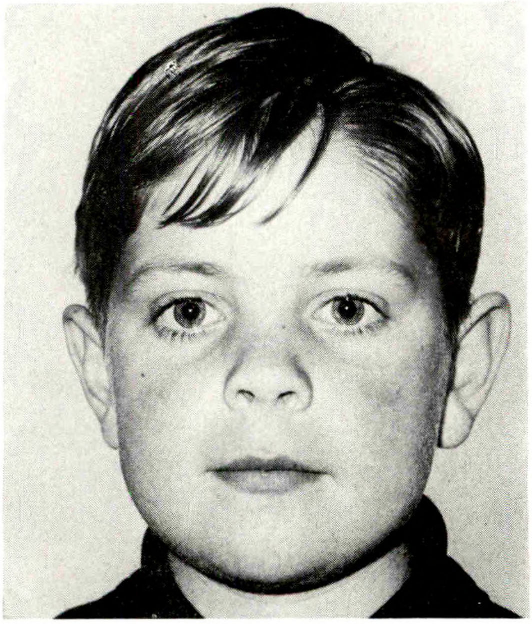

Fig. 1 *Facies in a child aged 8 years with isolated pulmonary stenosis.*

Subjects and methods

Contour maps were made of the faces of 20 children (boys and girls) with PS, confirmed by cardiac

JAMES HUNT, systems leader

catheterisation or surgery. The patients came from Guy's and Brompton Hospitals. A control group of 20 normal children was obtained from Salomon's Centre, Guy's. Both groups of children were between ages 6 and 10½ years. The mean age of the PS group was 8 years (SD 1·66) and the mean age of the control group was 7·8 years (SD 1·42).

The contouring technique used has been described (Ainsworth and Joseph, 1977). Parallel slits of light were projected on to the subject's face, forming contours. They were photographed from a position perpendicular to their planes of projection. Plano-convex lenses, interposed in each optical path, prevented the light slits from diverging from their source and eliminated perspective distortion in the photograph. Full contour coverage of the face was achieved by rotating the head and taking multiple exposures. The exposures were orientated to a datum plane by an optical sighting system and linked by caliper measurements from life.

A life size contour map was drawn from each picture, producing a geometrically interrelated set of maps for each child. The sets of contour maps were processed by computer and sections of the face were drawn at the four levels, shown in Fig. 2, which also shows the landmarks used. The sections were confined to the maxillary region because we suspected that the most characteristic features of the pattern were in this area.

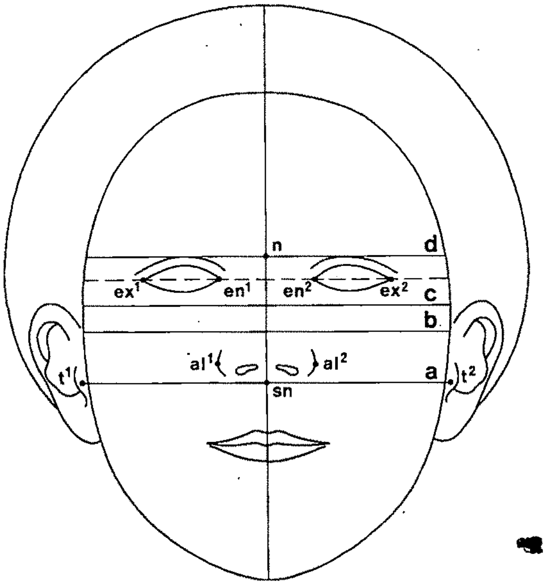

Fig. 2 *Landmarks and parallel planes of sections. Section (a) is defined by t^1, sn, and t^2. Section (b) is midway between section (a) and a horizontal line intersecting the canthi. Section (c) bisects the distance between section (b) and the canthi horizontal. Section (d) intersects (n).*

Table 1 *Measurements (A) of facial length, breadth, and height used for selecting the denominator of the facial index*

Measurements	*Fig.*	*No.*	*Control*		*Pulmonary stenosis*	
			Mean	*SD*	*Mean*	*SD*
Length	3	2	86·67	5·16	88·21	3·61
		63	74·50	3·85	76·25	4·02
Breadth	3	1	129·63	6·43	129·10	6·06
		41	124·90	6·73	124·30	6·03
Height	6	80	101·90	8·10	102·50	6·66

Facial proportion index. The variation caused by differences in facial size between individuals was eliminated by calculating ratios (R) rather than by giving actual measurements. By comparing real, or absolute measurements (A), a suitable dimension was selected, and in each face the remaining measurements were expressed as percentages of this dimension. This provided a proportion index which produced ratio (R) values and enabled a more precise comparison to be made.

Initial investigation was confined to measurements (A) of facial length, breadth, and height (Table 1). Length was expressed by two measurements at different heights in the midsaggital plane (2 and 63). Breadth was expressed by the intertragal dimension (1) and the bizygomatic diameter (41), and height by the distance between the nasion and gnathion (80). The most reliable measurement for use as the denominator of the facial proportion index was the intertragal dimension (1), since it was measured by calipers from life between distinct landmarks.

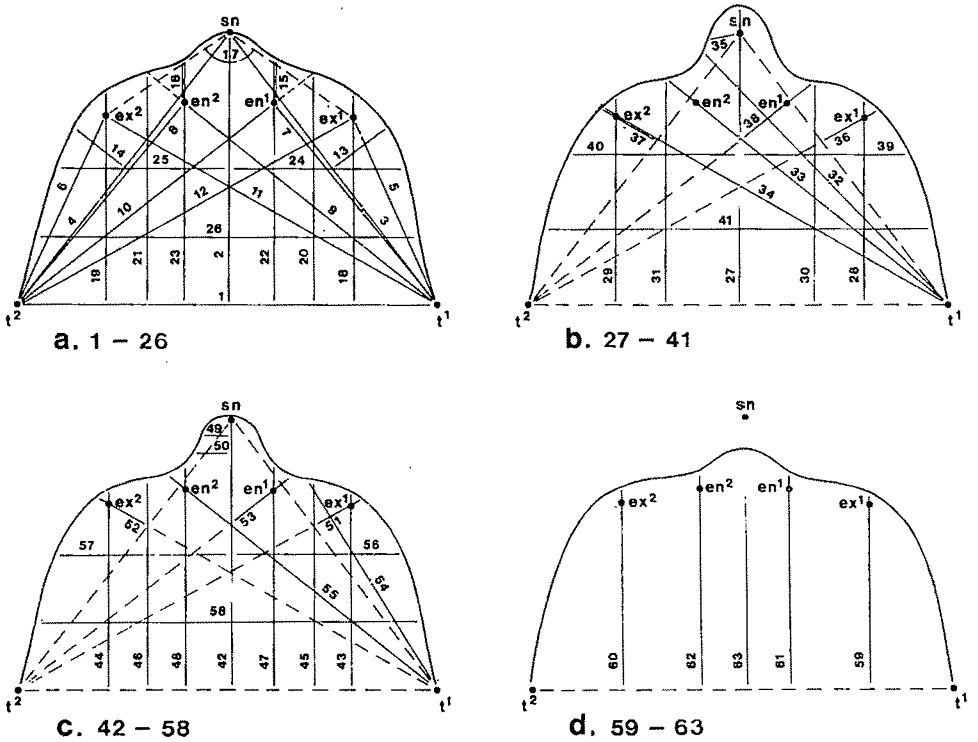
Thus the facial proportion index is:

$$\frac{\text{absolute measurements (A)} \times 100}{\text{intertragal measurement } t^1\text{—}t^2} = \text{ratio value (R)}$$

Results

Fig. 3 shows measurements 1–63 from which the mean values (R) for each group were used to construct composite sections at the levels (a), (b), (c), and (d). Broken lines represent the PS group, and continuous lines the control group (Fig. 4).

Sections (a). More measurements contributed to this pair of sections than to the other three pairs. Once the positions of the landmarks are established they remain common to all sections. It can be seen in Fig. 4 that the broken line is more prominent than the continuous one. In addition, in the PS group, the positions of both pairs of lateral and medial canthi



a. 1 – 26

b. 27 – 41

c. 42 – 58

d. 59 – 63

Fig. 3 *Measurements in sections (1–63). Continuous lines indicate the distances measured. Where a line is both continuous and broken, the continuous part represents the distance measured. Values for these measurements are shown in Tables 2, 3, 4,* and *5.*

and the subnasal landmark are also more prominent and consistently offset to the left. In Table 2 measurement 5 is significantly greater in the PS than in the control group ($P<0 \cdot 001$) and so are 3, 16, 18, and 20 ($P<0 \cdot 01$), as well as 7, 22, and 23 ($P<0 \cdot 05$). Measurement 17 is significantly less in the PS than in the control group ($P<0 \cdot 05$).

The offset positions of the landmarks affect diagonal measurements originating from the tragi. Measurements 3, 5, and 7 from t^1 are significantly different between the PS and control groups because the landmarks are offset in the direction of the measurements. The opposite measurements 4, 6, and 8 from t^2 are not significantly different because the landmarks are offset approximately at right-angles to the direction of the measurements. Consequently, in the remaining sections the measurements were chosen carefully to exploit fully the differences observed. Therefore, the majority of diagonal measurements originate from or are related to t^1.

Sections (b). The PS section is more prominent. In Table 3 measurement 28 is significantly greater in the PS than in the group ($P<0 \cdot 01$) as are measurements 27, 30, 32, 33, and 38 ($P<0 \cdot 05$).

Section (c). The PS section is more prominent. However, the actual shape of the section, irrespective of prominence, is distinctly different at the side of the nose. The curve is more gradual compared with the sharper and more angular shape of the control section. In Table 4 measurements 43 and 54 are significantly greater in the PS than in the control group ($P<0 \cdot 01$) and so are 42, 44, 45, 47, 48, and 53 ($P<0 \cdot 05$).

Sections (d). Five measurements are sufficient to identify the sections above the upper eyelids and through the nasion. A curve was drawn through the co-ordinates of each section. The PS section is more prominent. In Table 5 measurement 59 is significantly greater in the PS than in the control group ($P<0 \cdot 01$) and also 61 ($P<0 \cdot 05$).

Asymmetry. Of the 25 significant measurements between the PS and control groups in the sections,

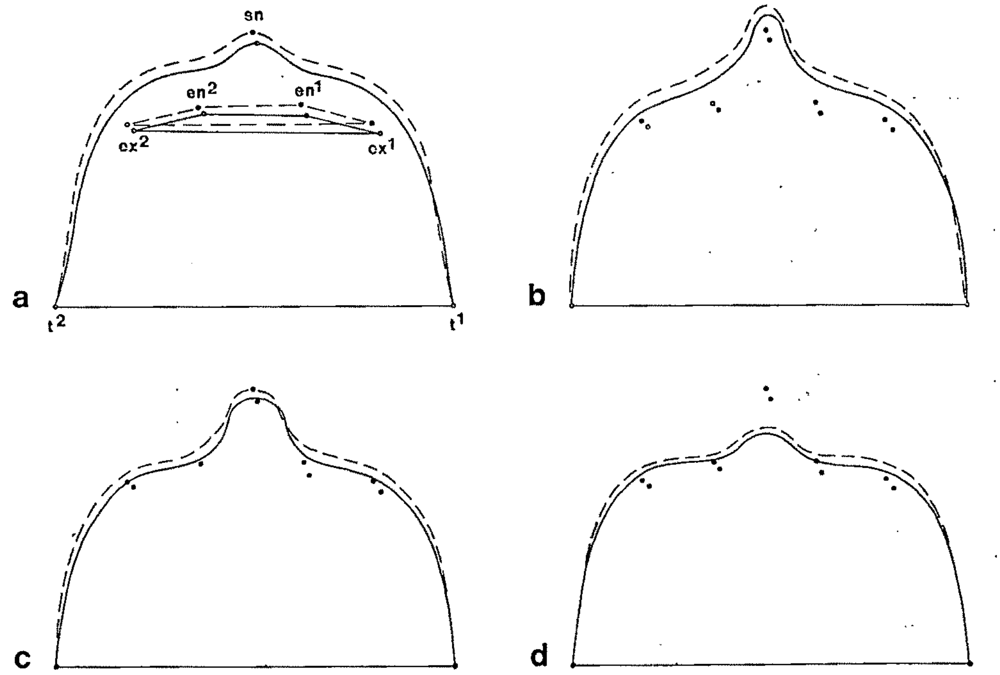


Fig. 4 *Composite sections, viewed from above, which were constructed from the mean (R) values in each group. Broken lines show the shape of the face in the PS group, and continuous lines show the shape of the face in the control group. In section (d), points representing the positions of the four canthi in each group have been joined. Broken lines indicate the PS group and continuous lines the control group.*

measurements on the right; this suggests that an asymmetrical pattern is present.

In each group asymmetry was measured by the differences between corresponding measurements on opposite sides of the face. The two most interesting pairs are 5 and 6, and 59 and 60, which both show differences at the 1 % level between the two groups.

The opposite asymmetrical tendencies of both groups explain why, when coupled with greater anteroposterior measurements in the PS group, the majority of differences in the sections are on the right.

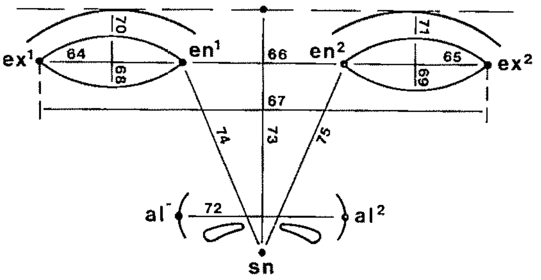

Fig. 5 *Measurements relating to the eyes and nose (64–75). Values for these measurements are shown in Table 5.*

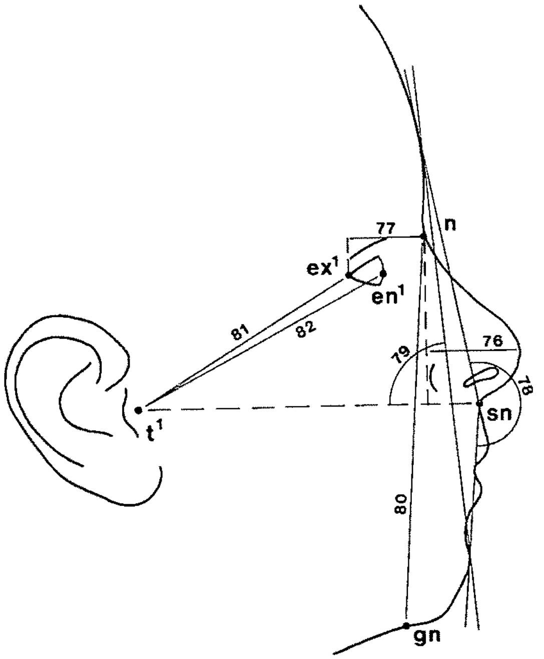

Fig. 6 *Lateral measurements in the midsaggital plane (76–80) and in 3 dimensions (81 and 82). Values for these measurements are shown in Table 5.*

Eyes, nose, and side of the face. The values for measurements associated with these components are shown in Table 5. Fig. 5 identifies measurements 64–75, and Fig. 6 identifies measurements 76–82. The height of the right palpebral fissue (68) is greater in the PS group (P<0·05).

The maximum width of the lower portion of the nose between the alae (72) is greater in the PS than in the control group (P<0·05). There is little difference in the length of the nose (73), although in the PS group it is slightly longer as are the other measurements of nasal length (74 and 75). Prominence of the tip of the nose (76) is marginally greater in the PS group. The bridge of the nose at the nasion (77) is similar in both groups.

The maxillary angle (78) is similar in both groups. The facial angle (79) is particularly so. There is no difference in the measurement of facial height (80). The 3-dimensional distance between t^1 and ex^1 (81) is significantly greater in the PS than in the control group ($P<0·001$). The 3-dimensional distance between t^1 and en^1 (82) is also significantly greater in the PS than in the control group ($P<0·05$).

Statistical analysis. Of the 83 variables, 29 showed significant differences at the 5% level. This suggests that, for a particular individual, it may be possible to predict to which group, control or PS, he is likely to belong. The theory of discriminant analysis (Fisher, 1938; Rao, 1952; Hills, 1966; Armitage, 1971) gives rules for constructing a function of a set of variables, such that the sign (positive or negative) of the value of the function predicts the group (control or PS).

The best set of two variables consisted of 5 and 16. Their values are represented by points on a scatter diagram (Fig. 7). Points above the line correspond to positive values of the discriminant function—that is, individuals classified into the PS group. Four children with PS were misclassified as belonging to the control group, and one child was misclassified as belonging to the PS group.

The classification can be improved by using more variables. In Fig. 8 histograms for each group are shown for six variables.

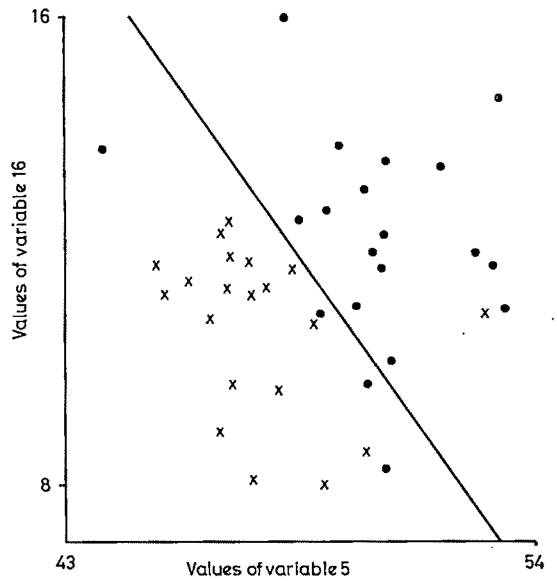

Fig. 7 *Discrimination from two measurements between the group of control children (X) and group with PS (●).*

The error rate of a discriminant function—that is the proportion of individuals it will misclassify—may be estimated by applying it to both groups of children. This will underestimate the error rate to be expected when used on other individuals, as the discriminant function has been chosen as the best for the sample groups. The estimate of Lachenbruch (1965) avoids this bias and gives a more accurate estimation. This is shown in Table 6 for several sets of variables. The error rate for six variables is now estimated as 4, as opposed to 2 in Fig. 8, where Lachenbruch's estimate was not applied.

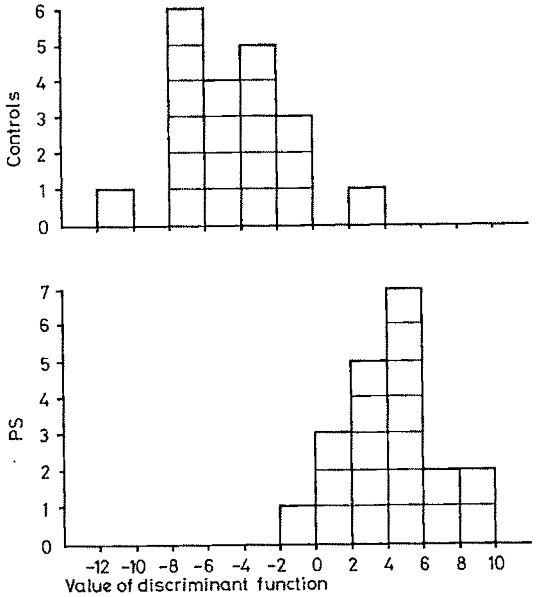

Fig. 8 *Histogram of discriminant function of variables 5, 16, 33, 44, 47, and 59.*

Discussion

Statistical analysis proves that children with PS have a distinctive facial pattern. Measurements can discriminate between both sample groups, classifying between 34 and 37 of the total of 40 children as either PS or control, according to the number of variables used.

All anteroposterior measurements in the sections, whether significant or not, are greater in the PS than in the control group. The majority emerge from a common source, a vertical plane coincident with the intertragal dimension t^1–t^2 (intertragal base plane).

In the PS group the face is longer from the intertragal base plane. A notable feature is the prominence of the subnasal and canthi landmarks, with correspondingly more prominent sections. However, the relationship between the forward landmarks in both groups, and the maxillary region considered in isolation without reference to the intertragal base plane, is much more subtle. For example, the positions of the four canthi, relative to each other in each group, are almost identical. Consequently, it is appropriate to consider the differences in two ways. Firstly, to devote special attention to the maxillary region, ignoring its relationship with the intertragal base plane, and secondly, to consider overall differences relative to the intertragal base plane which are responsible for the increase in facial length of the PS group.

Maxillary region. Comparisons can be made using the composite sections as a visual guide, but superimposing the canthi. The sections (a) for each group are different in shape. The PS section shows that the cheeks are slightly wider and more rounded. Measurement 16, which is highly significant, supports this and shows that there is a more prominent distribution of soft tissue in the cheeks continuing round to the sides of the nose adjacent to the alae. The position of the PS subnasal landmark (sn) is more prominent, and the angle ex^1 sn ex^2 (17) is less in the PS than in the control group, indicating more tissue at this point in front of the maxilla. This general 'bulge' becomes less pronounced in the other sections, but nevertheless is supported by two significant measurements, 38 in section (b) and 53 in section (c). The tissue covering the zygomatic bone resumes the same form as the control group.

In the region of the nose, the curve of the PS section (c) is more gradual than the steeper and more angular curve of the control section. Measurement 53 supports this. The sides of the nose near the bridge seem to be filled with excess soft tissue. This trend continues down the sides of the nose becoming less and finally ending in a significant increase in the width of the nose between the wings (72). There is probably more cartilage at the sides of the nose and the tissue of the alae is more developed laterally.

Although the palpebral fissures are the same length and distance apart in both groups, the height of the right palpebral fissure (68), being significantly greater in the PS than in the control group, gives the eye a more rounded appearance with a slight decrease in height of the right upper lid. It is possible that a similar impression is produced in the left eye, but the actual measurements are not very different.

It can thus be seen that the differences in the maxillary region indicate different distributions of tissue in the PS group.

Anteroposterior differences. The much greater anteroposterior dimensions in the PS group could be caused by the maxillary region advancing anteriorly as a result of (1) excess tissue in that region only, or (2) excess tissue in the maxillary region, combined with a longer skull. Alternatively, the tragi may be situated more posteriorly as a result of (3) excessive posterior growth of the tragi, or (4) the complete ear is set back by a longer skull displacing the external auditory meatus. There could be a combination of these factors. However, it is clear that the differences are due either to soft or hard tissue, or to a combination of both. A definite conclusion, even with a detailed analysis of the skull, would be difficult to reach because different combinations of abnormal components can produce the same effect. Nevertheless, several points are worth noting.

If (1) is wholly or largely responsible, and the eyeballs remained in the same relative position to the intertragal base plane in both groups, the length of the palpebral fissures in the PS group would be very much less. The measurements confirm they are not. Therefore the eyeballs would have to be more forward in the orbits to bring their perimeters out to the more prominent positions of the PS canthi, which would be displaced anteriorly from the lacrimal and zygomatic bones due to a substantial increase in tissue around the eyes. This would mean that the eyeballs are being forced forwards in their orbits.

If (2) is responsible, the eyeballs would remain in the same relative positions to their orbits, and the canthi would be much the same distance from the bone in both groups.

It seems unlikely that (3) is involved to a large extent, as the ear would assume a very odd appearance which we did not observe.

It has been shown that a more prominent distribution of tissue in the maxillary region accounts for a portion of the increase in facial length in the PS group. We think it is probable that, quite apart from altering the appearance and shape of the face in this region, an excess of tissue distributed throughout this area is wholly responsible for the greater anteroposterior measurements in the PS group.

Relationship to other organs. Since the face is repeatedly being looked at, the observer becomes skilled in discriminating between differing facial patterns. It is the subtle blending, structural form, relative sizes and shapes of the parts of the face which are responsible for differing facial patterns. In diseases not apparently affecting the form of the face, knowledge of its morphology may still be relevant. Thus it is conceivable that more subtle variations in the anatomy of the face are present which can be identified only by precise measurements. The face could be affected by some of the disturbances which have occurred in other organs during development.

In the normal developing fetus we do not know whether the embryological parts progress independently in an unrelated order, or fit into a precise system in an accurately timed sequence. If our tissues and organs do depend on one another for their origin and form, then we must base our observations on analysis of the embryo as a whole rather than restriction to individual organs. Any marked departure from normality in one organ might therefore be accompanied by maldevelopment in many other organs. Thus the facial pattern in children with PS may be an example of this interdependence of the form of various organs.

We thank Professor M. J. R. Healy for statistical advice, Dr P. Zorab and Dr T. Mann for constructive criticism, Miss M. Theisen of the Salomon's Infant Welfare Centre, Guy's Hospital, for providing the control group, the parents who responded to our appeals for volunteers, Mrs S. Cowley for secretarial help, and the Special Trustees, Guy's Hospital, and the Lane Fund, Brompton Hospital, for financial support.

A. P. WATERSON

*Department of Paediatrics and Neonatal Medicine, and Department of Virology,
Hammersmith Hospital, and Queen Charlotte's Maternity Hospital, London*

SUMMARY 126 children of 102 hepatitis B surface antigen (HBsAg) carrier mothers were delivered at Hammersmith Hospital and Queen Charlotte's Maternity Hospital, between 1971 and mid-1978. Blood tests on 110 of these children showed that 8 out of the 18 with Chinese mothers, but only 6 out of the 92 other children, have become HBsAg positive. The presence of maternal hepatitis B e antigen (HBeAg) is also significantly correlated with transmission of HBsAg to the children. The management of children whose mothers are carriers is discussed.

Since the discovery of hepatitis B antigen (Australia antigen) in 1965 leading to the identification of the causative agent of hepatitis B (Blumberg *et al.*, 1965; Prince, 1968; Krugman and Giles, 1970), awareness of its position as a major source of both acute and chronic disease has been growing (Ohbayashi *et al.*, 1972; Kattamis *et al.*, 1974; Dupuy *et al.*, 1975; Welsh *et al.*, 1976). Sensitive and rapid tests for the detection of the whole virus (HBV) and its components, the surface antigen (HBsAg) and core antigen (HBcAg) are now available, and these have contributed to our knowledge about the prevalence and modes of transmission of HBV. Besides these antigenic particles and their corresponding antibodies (anti-HBs and anti-HBc), other markers have been found in association with HBV, notably hepatitis B 'e' antigen (HBeAg) and anti-HBe (Magnius *et al.*, 1975).

It is known that the prevalence of HBV varies geographically, and is estimated to be 0·1% in northern Europe and North America, but up to 20% in Taiwan (Shih *et al.*, 1971; Gerety *et al.*, 1974; Helske, 1976; Chen and Sung, 1977). Modes of spread of the virus include direct or accidental inoculation of infected blood or blood products through transfusion, intravenous drug abuse, tattooing, acupuncture, dental work, shared razors, laboratory accidents, and perhaps insect vectors (Metselaar *et al.*, 1973; Patterson *et al.*, 1974), sexual contact (Heathcote *et al.*, 1974b), and 'vertical' transmission from mother to baby (Turner *et al.*, 1971; Merrill *et al.*, 1972; Papaevangelou *et al.*, 1974; Anderson *et al.*, 1975; Stevens *et al.*, 1975), probably through ingestion or passage of blood through broken skin or mucous membranes during delivery. Most body fluids, including saliva (Bancroft *et al.*, 1977), sweat (Telatar *et al.*, 1974), semen (Heathcote *et al.*, 1974a), pleural fluid (DeFlora and Forci, 1977), breast milk (Krugman, 1975), and blood may contain the virus. Horizontal spread in ways other than through blood seems likely but has not been well defined (Szmuness *et al.*, 1975).

As the virus is able to persist in man for long periods (after acute hepatitis or without detectable illness), producing so-called 'carriers', defined as those in whom HBsAg is present for more than 6 months (World Health Organisation, 1977), it would appear that a large reservoir may preclude its eventual eradication.

Through screening and the gradual elimination of HBsAg-positive carriers from panels of blood donors, once an important source of hepatitis, vertical transmission may rapidly become the principal means of viral spread, especially in countries with a large number of carriers. One report (Derso *et al.*,

1978) indicated that certain ethnic groups, particularly the Chinese, may be genetically prone to such transmission, and the increased risk does not appear to be related to the birthplace of the mother but to her ethnic origin. We report here a study based on all the infants delivered of HBsAg-positive carrier mothers at two hospitals in west London, the Hammersmith Hospital and Queen Charlotte's Maternity Hospital. This study appears to confirm earlier work. Some of the mothers from the Hammersmith Hospital were the subject of a previous report (Waterson *et al.*, 1977).

Methods and subjects

Since July 1971 at Hammersmith Hospital, and since January 1972 at Queen Charlotte's Maternity Hospital, all antenatal patients have been screened for the presence of HBsAg. From those dates up to August 1978, a total of 102 HBsAg-positive carriers have been detected who subsequently delivered 126 live infants. There were no stillbirths. The total number of deliveries during those periods in the two hospitals was 33 467, giving a prevalence of 0·4 per 1000 deliveries. Ten abortions, 6 acute cases of hepatitis, and 6 cancelled bookings of carrier mothers have been excluded, as we were only interested in liveborn infants of carriers.

Cord blood samples were sent in the early years of the study for HBsAg screening by gel diffusion or immunoelectrophoresis, and after 1974, by direct passive agglutination (Hepatest, Wellcome). In a few cases that were positive, a sample of the baby's blood was also tested. 60 cases in which the cord blood was negative were also sent for radioimmunoassay (RIA) testing (at the Public Health Laboratory Services, Colindale, London).

Between February 1972 and May 1974, 8 randomly selected infants whose cord bloods were negative were given 1 ml (100 mg) of hepatitis B immune globulin (HBIG) at birth, and one was given 2·5 ml at birth. A further 10 infants were given 1 ml of HBIG at birth with a single repeat of this dose between 2 and 8 months, if blood was still negative for HBsAg. This trial was stopped in 1974.

Breast feeding was allowed freely, as we agree with other workers (Beasley *et al.*, 1975) that transmission of virus through breast milk and/or ingestion of blood from excoriated nipples is negligible compared with the infant's exposure to contaminated maternal blood at delivery and subsequent close contact at home.

Mothers were asked to bring their children to the clinic at intervals up to age 2 years for testing of HBsAg, both of their infants and themselves. The infant's liver function tests were also requested if sufficient blood had been obtained.

In August 1977, an effort was made to recall all the children for physical and developmental examinations and repeat blood specimens. Liver function tests were obtained if possible, and in about half of the cases, if blood was negative for HBsAg by Hepatest, a sample was sent for further RIA testing (PHLS, Colindale).

93 of the 102 mothers were also tested for the presence of HBeAg and anti-HBe by agar gel diffusion (by M. Supran, PHLS).

Results

Mothers. The birthplaces and ethnic origins of the 102 carrier mothers and the numbers of children are given in Table 1. No mother had clinical signs of hepatitis at any time during pregnancy or follow-up. Of 58 mothers who had liver function studies done, 5 had abnormal results at least once, and of these, one was positive for HBeAg, one positive for anti-HBe, and 3 were not tested for either.

It is of interest to note that 21 of the 102 mothers had worked in hospitals before the discovery of their HBsAg carrier state. Several were nurses who had had contact with jaundiced patients or those undergoing haemodialysis.

Table 1 *HBsAg-positive carrier mothers*

No. of mothers (n = 102)	*Ethnic origin*	*Places of birth*	*No. of children delivered (n=126)*	*No. followed up (n = 110)*	*No. HBsAg+ after 1st week (n = 14)*
15	N. European	France, Poland, Uganda, UK	17	14	2
13	S. European	Cyprus, Greece, Italy, Yugoslavia	17	14	0
3	N. African	Egypt, Morocco	4	4	0
41	W. African	Aruba, Gambia, Ghana, Grenada, Guyana, Jamaica, Nevis, Nigeria, St Kitts, Sierra Leone, Trinidad, UK, USA	51	44	3
1	E. African	Uganda	1	1	0
19	E. and S.E. Asian	Brunei, Hong Kong, Japan, Malaysia, Mauritius, Philippines, Singapore	23	20*	8†
5	S. Asian	Bangladesh, Guyana, India, Pakistan, Trinidad	6	6	1
5	S.W. Asian	Iran, Iraq	7	7	0

*18 had Chinese mothers, †all had Chinese mothers.

Table 2 *HBeAg status of 93 mothers and HBsAg status of their children*

Mother's status (n=93)		*Children*		
		HBsAg+	*HBsAg−*	*Unknown*
HBeAg+	10 (7 Chinese)	9	3	2
Anti-HBe+	38 (2 Chinese)	3	42	2
Neither found	45 (5 Chinese)	2	45	9

The HBeAg status of the 93 mothers tested for this is given in Table 2. Chinese mothers are much more likely than nonChinese mothers to be HBeAg positive ($P<0{\cdot}001$). Eight of the 10 HBeAg-positive mothers produced 9 of the 14 HBsAg-positive children. Of the remaining 2 HBeAg-positive mothers, one was Japanese and had 3 children, all HBsAg negative. We were unable to follow up the child of the other mother.

Children. Of the 126 children 53 (43%) were girls. We were able to see 110 after the first week of life. The mean age of follow-up was 24·8 months (range 2 months to 5 years 9 months). Three of the remaining 16 had died (one due to congenital heart disease at age one week, and 2 due to cot deaths at ages 3 and 16 months), and 12 could not be located or had parents who refused to allow blood to be taken. From one child, in Malaysia, a blood sample could not be obtained in spite of several attempts.

The results of cord blood testing are given in Table 3.

14 (13%) of the 110 children were later HBsAg-positive, 4 by RIA testing only. Details are given in Table 4. Five of the 14 were girls. All the children were growing and developing normally, and no hepatomegaly was found. Alanine transaminase (ALT) results were normal in the 9 positive children who were tested. Two of the 14 positive children had received 1 ml of HBIG at birth only; the rest received none. Table 4 shows that 8 of the 13 mothers were positive for HBeAg, and in fact 7 of these 8 were Chinese. In 2 of these Chinese families, both with HBeAg-positive mothers, we were able to test siblings; in one, the sibling was found to be positive, while in the other, she was negative. Six of the 13 fathers were tested and all were HBsAg negative.

Table 3 *Positive cord bloods*

Cord blood		*Children*		
Positive on initial screen	*Positive by RIA only*	*Later HBsAg+*	*Later HBsAg−*	*Lost to follow-up*
9		1	6	2
	10*	3	7	0

*One child positive by RIA only at birth was positive by Hepatest at 2 months, but negative by both RIA and Hepatest at 6 months.

Table 4 *HBsAg-positive children*

Case	*Mother's birthplace*	*Mother's ethnic origin*	*Age first+ (months)*	*Cord+?*	*Mother's HBe status*
1*	UK	N. European	15†	No	anti-HBe
2*	UK	N. European	2	No	Neither
3	Nigeria	W. African	6	No	anti-HBe
4§	St Kitts	W. African	36‡	No	HBeAg
5§	St Kitts	W. African	30‡	No	HBeAg
6*	Bangladesh	S. Asian	30‡	Yes	Neither
7*	Malaysia	Chinese	1½	No	anti-HBe
8	Hong Kong	Chinese	16‡	No	HBeAg
9	Mauritius	Chinese	1½	Yes	HBeAg
10	Hong Kong	Chinese	3	No	HBeAg
11	Hong Kong	Chinese	7	No	HBeAg
12	Malaysia	Chinese	5	No	HBeAg
13	Malaysia	Chinese	3	Yes	HBeAg
14	Singapore	Chinese	5	Yes	HBeAg

*Positive by RIA testing only; †negative at 3, 6, and 12 months by RIA, but positive at 15 and 24 months by RIA; ‡these children were not tested before these ages; §siblings.

As noted in Table 4, one of the children (Case 1) was negative when tested at ages 3, 6, and 12 months, but at ages 15 and 24 months she was RIA positive. This may indicate some form of horizontal transmission. Her father was negative for HBsAg.

There was no significant difference in the incidence of breast feeding between the groups of positive and negative children.

Discussion

Our results reflect the mixed ethnic origins of the population in London and seem to confirm the findings of others regarding a racial tendency to vertical transmission of the HBV, as detected by the presence of HBsAg. There have been interesting theories regarding the genetics of such transmission (Hug, 1976; Blumberg, 1977).

Some recent work has dealt with the sex distribution of carriers, as more men than women are carriers (Goodman *et al.*, 1971; Curtis *et al.*, 1973), and it also seems that where one parent is a positive HBsAg carrier, there is an increased secondary sex ratio (number of males per 100 females) (Drew *et al.*, 1978). Our 102 mothers have produced, to our knowledge, a total of 223 children, 125 (56%) boys and 98 (44%) girls. The numbers are too small for valid analysis, however, and complete data are not available.

Our cord blood results, as those of others (Aziz *et al.*, 1973), would appear to show the unreliability of such specimens in predicting the future HBsAg status of the child. Contamination with maternal blood may account for most if not all positive cord bloods; in several cases in which cord blood was positive, a blood sample from the infant was checked and found to be negative. In fact, at Hammersmith Hospital cord blood testing is no longer done;

instead a specimen is taken from the child some time during its first week of life. *In utero* transmission has been reported but is thought to be rare (Schweitzer and Spears, 1970), and usually comes not from carrier mothers but from overt cases of hepatitis during the last trimester of pregnancy or early in the postpartum period (Schweitzer *et al.*, 1972, 1973).

The HBeAg positive state of the mother increased the transmission of HBV to the child, as has been shown by others (Beasley *et al.*, 1977; Chaudhuri *et al.*, 1977; Gerety and Schweitzer, 1977; Murata *et al.*, 1977). Anti-HBe was not necessarily protective, as can be seen from Table 2, although this has been suggested (Okada *et al.*, 1976). There are those who now say that HBeAg may not be a marker of HBV but an indication of liver damage (Fay *et al.*, 1977; Tiku *et al.*, 1977; Vyas *et al.*, 1977); we did not have adequate maternal liver function studies to be able to corroborate this.

The infants, therefore, who were at greatest risk from vertical transmission of HBV in our study were those whose mothers were Chinese and/or HBeAg positive. This raises the question of passive protection such as that recommended by the World Health Organisation (1977) for a single acute exposure—one might argue that during parturition this is the type the child receives. The two positive children who received only a single dose of HBIG at birth might have benefited from larger, repeated doses (Dosik and Jhaveri, 1978; Iwarson and Norkrans, 1978). It is concluded that an adequate trial of HBIG prophylaxis is not feasible in London or elsewhere in the UK, where there are so few carrier mothers.

Concerning the continued surveillance of the children with HBsAg-positive mothers, we would agree with those (Melnick *et al.*, 1976; Woolf and Williams, 1976; Barker *et al.*, 1978) who feel blood should be tested at birth, 6 months, and 12 months, and if the child remains negative, he could be discharged (although we did have one conversion after this age). In the case of children found to be positive, yearly examinations and liver function tests for life ought to be considered. This would not necessarily be adequate in diagnosing chronic active hepatitis or hepatocellular carcinoma, but at least one's index of suspicion would be high. It would seem that very long-term follow-up studies will be needed before questions such as the necessity for frequent liver biopsies can be answered adequately. Management of the carrier has been discussed at length (Cossart, 1977).

Mothers, too, ought to be referred for follow-up in medical clinics once their obstetric need has ended (Babb, 1976). We found that few of the women were seen regularly except for antenatal care. We tended to be reassuring about good future health, despite the mounting evidence of possible liver disease later, as almost all our mothers were very upset at the idea of being 'infectious' and a few felt constrained in handling their new babies.

Mothers were warned about the need for care in handling their own blood from any source, as well as the need to inform their dentists and anyone who might later seek blood samples (general practitioners were officially informed). When a child was found to be positive we gave similar advice, but have found that perhaps the child's positive status should not be mentioned at school, as he may then be regarded with suspicion. One 6-month-old child in our study was rejected by a nursery as a result of this information, probably due to fear and ignorance by the nursery staff. There have been studies in schools indicating that crossinfection in groups of schoolchildren does not occur (Follett *et al.*, 1978).

Micromethods are being developed for HBV screening using finger prick blood samples on filter paper (Farzadegan *et al.*, 1978). Perhaps with the perfection of such methods, very large population studies may become feasible.

We thank Mr A. Holley and Mr T. Ross of the Virology Departments of Hammersmith Hospital and Queen Charlotte's Maternity Hospital for their help, as well as the children, their families, and the many housestaff who made the study possible.

Received 5 December 1978

Nathalie Masse

Nathalie Masse Research Fellowship. This is intended to help young workers engaged in research on problems in social and preventive paediatrics. It was granted for the first time in 1978 and will subsequently be granted in every even-numbered year. The next fellowship will be awarded in 1980, for which applications are invited by 31 December 1979.

International Nathalie Masse Prize. This prize of 10 000 French francs was created to reward original work concerning childhood, presented either by an institution or by an individual under 40 years, with a view to encouraging studies by young professionals and research workers. The prize will be awarded for the first time in 1979 (the list for this is now closed), and thereafter in every odd-numbered year. The next award will be in 1981 for which applications are invited by 1 September 1980.

All grant and prize winners will be chosen without regard to nationality by an international jury.

Details and application forms for the fellowship and prize are obtainable from the Memorial Committee, International Children's Centre, Château de Longchamp, Bois de Boulogne, 75016 Paris.

Childhood cystinuria in New South Wales

Results in children who were followed up after being detected by urinary screening in infancy

ARABELLA SMITH, J. S. YU, AND D. A. BROWN

Health Commission of New South Wales, Oliver Latham Laboratory, and
Royal Alexandra Hospital for Children, Sydney, Australia

SUMMARY Homozygous cystinuria was diagnosed in 45 children and 19 of their siblings in the course of routine urine screening of 6-week-old infants in New South Wales. These children were followed for up to 14 years. During this time there were 5 clinical episodes of renal disease which could be ascribed to cystinuria. There was normal mental development in all the children except one. Of 49 children over 3 years, 4 had height centiles less than the midparent height centile, while 45 had height centiles equal to or above the midparent centiles. Family testing in these 45 cases showed that 60% were type I cystinurics, and 35% were of the mixed or compound type (5% were not classified). Data from the parents and grandparents showed that renal tract calculi had occurred in 14 of them. This study shows that children with homozygous cystinuria, detected by urinary screening in infancy, rarely have renal symptoms. Mental development was normal as was growth in height. There was an increased incidence of noncystine stone formation among the relatives of these children. The incidence of homozygous cystinuria in New South Wales is one in 17 286.

Cystinuria is a disorder of renal tubular and intestinal transport of amino-acids. the main clinical association being renal calculi formation. Colliss *et al.* (1963) reported a height deficit in cystinurics compared with the general population, and Scriver *et al.* (1970) suggested that mental retardation was an associated feature. Many cases of cystinuric stone formers have been described, mainly in adults, although in the study of Bostrom and Hambraeus (1964) in Sweden there were 9 children and adolescents, most of whom were identified by the clinical manifestations of calculus disease. We report the results in a group of children with homozygous cystinuria who were followed up after being identified by newborn screening of urine.

Methods

During a 13-year period (1964 to end of 1977), urine samples from 950 767 6-week-old babies in New South Wales, 85% of the infant population, were examined by unidimensional paper chromatography (Wilcken *et al.*, 1973). If this first urine test showed markedly raised levels of cystine, lysine, or arginine (ornithine is not well separated by this method) a repeat test was requested. These first two tests were performed on urine-soaked blotting paper slips, but if the second test also showed a gross aminoaciduria consisting of cystine, lysine, or arginine, a liquid urine specimen was requested. A definitive diagnosis of homozygous cystinuria was made if this test showed high levels of cystine, lysine, and arginine, the baby usually being 6 months by this stage.

Children with homozygous cystinuria were seen for initial assessment and then at least yearly. At each visit they were assessed clinically, their general health was assessed, and their parents were also questioned specifically about the occurrence of back ache, abdominal pains, renal pain or colic, haematuria, frequency of micturition, and scalding of urine. They were asked about any medication the child had received, the diet, and details of fluid intake. Height and weight (without shoes) of the affected children

J. S. YU, medical superintendent

were measured as were also the heights and weights of the siblings and parents seen at the follow-up. No correction was made for parent's age, all being under 40 years of age. The children's height centiles and the midparent height centiles were calculated using the tables of Tanner *et al.* (1970). The parents were encouraged to bring the whole family to each visit and unaffected siblings were also seen several times in most families.

Formal IQ testing in these patients was not routinely done. Achievement of milestones was recorded and parents were asked to rate the development of the child as slower than, the same as, or quicker than that of unaffected siblings. Children who had completed at least 2 years of schooling were assessed by their school reports and their class level for the age. If they were in the top class for the age grade, they were rated as good, if in the middle class as average, and if in the lowest class they were rated as slow. Their school level was also compared with their siblings.

The management of the children was the same in all cases, namely increased fluids to the limit of tolerance. None of the children had been given urinary alkalinisers, D-penicillamine treatment, or protein restriction at the time of this report. Four children (from 2 families) were investigated biochemically on a number of occasions, but have not been seen by us. Information was obtained from the family doctor by means of a specific questionnaire, as described above.

At each follow up, a sterile midstream specimen of urine was obtained and this was immediately set up for microurine analysis by standard methods. Urinary amino-acids were examined at each visit by high voltage electrophoresis, cystine was estimated quantitatively (Rootwelt, 1967), the presence of excess arginine confirmed by the Sakaguchi reaction (Smith, 1969), and cystine crystals were sought using the method of Hepler (1950). These examinations were performed on fasting first morning urine specimens in most patients but in some of the older ones on a 24-hour urine specimen. In 4 cases, urinary amino-acids were estimated on a Beckman Unichrome amino-acid analyser.

Once the patient had reached age 4 or 5, a plain *x*-ray of the abdomen was taken to exclude the presence of a calculus, and this was repeated 2 or 3 years later in some of the older patients. A detailed genetic history was also obtained at the initial visit with specific questioning about family history of renal calculi, consanguinity, and abortions, as well as about more general genetic conditions. Urine specimens from both parents and all siblings were tested in each family; in some families other family members were also tested.

Results

Of 950 767 babies tested between the start of screening in 1964 and the end of 1977, 45 were found to have cystinuria, 19 of 89 siblings tested were also affected, giving a total of 64 known cases (Table 1). 38 were boys and 26 girls, giving a sex ratio of 0·59 ($P>0·2$). Ten of the 19 homozygous siblings were born after the propositus and are shown as propositi themselves in the incidence figures and in the discussion of initial urinary test findings. In one family 2 affected siblings of the propositus were unlike twins, and in another family with twins, one was homozygous and the other normal. The ages of the 64 children are shown in the Figure.

Initial urine testing showed a typical aminoaciduria

Table 1 *Siblings of the cystinuric propositi*

Propositi (n = 45)	*Siblings*			
	Homozygous	*Heterozygous**	*Normal*	*Total*
Boys (n=28)	19–10	18–11	52–33	89–54
Girls (n=17)	– 9	– 7	–19	–35

*From 16 mixed or compound families.

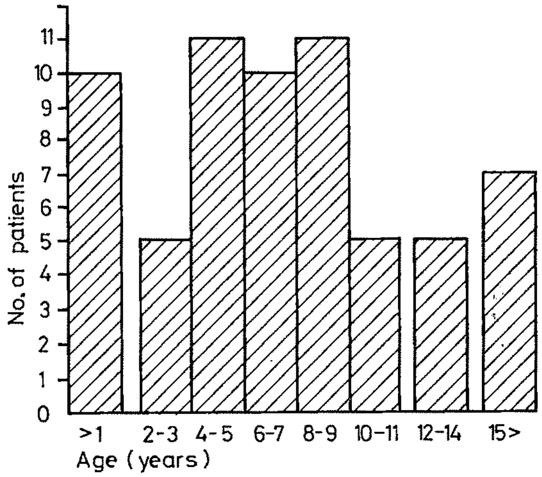

Figure *Age of 64 homozygous cystinuric patients. The scale for age ranges is not uniform, and changes in scale are shown by a space—for example the 12–14 block represents a 3-year period (1964–66), being years during which few cases were detected, and >1 block represents a one-year period (1977), a year in which there were many cases. The 7 patients, aged at least 15 years and born before 1964, were found when their families were tested. Two other siblings, older than the propositus (one 10, one 11 years), had not been screened in infancy and were also detected by family testing.*

at 6 weeks in 44 of 55 babies. In 11 patients, arginine was not detected in the first test, although the cystine and lysine levels were very high. Seven of these 11 patients showed the typical aminoaciduria in the second test; by this time the baby was usually 3 months. There were 4 boys in whom increased arginine excretion was not apparent at either of the first 2 blotting paper tests although cystine and lysine levels were very high; this was the indication for requesting a third test. Cystine, lysine, and arginine were all much increased in the subsequent liquid urine specimen in these children and have remained so.

Patients were definitively diagnosed at about 6 months, the 9 older siblings were diagnosed when family studies were undertaken. All were reviewed during the latter part of 1977 and first half of 1978. The age at last review ranged from 6 months to 22 years (oldest sibling) with mean age 7·6 years. 49 were at least 3 years and 28 were at least 8 years. Renal symptoms were present in 5 patients*. One boy had an episode of renal calculus formation at age 17½. One girl had episodes of right loin pain at 10½, and there were 2 cases of urinary tract infection, and a boy of 4 years had dysuria and a urinary tract infection; 4 months later a stone was detected on routine *x*-ray. There were also 3 children (2 boys, 1 girl) who were bed-wetters until about 9–10 years and there were 3 asymptomatic girls who showed urinary contamination, but not infection of urine, on routine microurine investigations at follow-up.

Routine *x*-rays of the abdomen had been performed in 42 of the children (in some of the older ones more than once) and in one case a calculus was seen which was asymptomatic. Routine tests for microscopic haematuria were negative in every patient at each follow-up.

The general health of the children was good and not significantly different from their siblings. There were 9 cases with noteworthy childhood conditions. One boy had a hemivertebra of L4 spine producing lumbar scoliosis; the adopted girl suffers from severe asthma requiring daily medication; one girl at 3½ years has grey carious irregular teeth; one boy aged 4 years had surgical correction of pyloric stenosis at 5 months; and one boy, free of renal symptoms, had a salivary gland calculus removed surgically at 7 years. Another boy aged 9 also had surgery for pyloric stenosis as a baby. One girl had mild minor retardation and attended the spastic centre until she was 5, and one boy had surgery for bilateral convergent strabismus. One further patient has petit mal epilepsy.

The growth of these homozygous cystinuric children appeared to be within the normal range. The mean birthweight was 3·07 kg (boys and girls combined) with a range of 1·76 kg (in a 7-week preterm girl) to 4·28 kg. In 5 babies the birthweight was low due to prematurity (including the twins), there were 2 term babies in whom the birthweight was low, but in all the others it was average. Birth length was not as consistently recorded as birthweight and was not known for 20 of the children, but in the remainder the mean birth length was 52·5 cm. Two children had birth lengths <3rd centile, the rest were between 10th and 90th centiles.

Height of the children at last follow up (of the 49 patients over 3 years) showed that 28 were on the same centile as their midparent height centile, 18 were above, and 4 were below this. Three of these children had unaffected siblings who were also below the midparent height centile, and the fourth, a 4-year-old boy, was on the 10th centile for height, the midparent height being on the 50th centile, but he was an only child and so had no siblings for growth comparisons. The heights of the parents of the adopted girl were not known, but she was on the 50th centile for height.

Results of genetic studies are shown in Table 2 using the genetic types as described by Rosenberg *et al.* (1966). In one case there were no family data as the patient had been adopted. In one family, the results of family testing could not be reconciled with current concepts of the genetic inheritance of cystinuria. Of the remaining 43 families, 27 were type I and 16 were of mixed genetic type, 6 in which both parents were carriers and 10 with one normal parent and one heterozygous parent.

The sex ratio among the siblings of the patients can be seen in Table 1 and is 0·5 for the homozygous siblings, 0·61 for the heterozygous siblings, and 0·64 for the normal siblings. Although there appear to be slightly more boys, particularly among the normal siblings, this was not significant (P>0·1). Data for sex ratio of newborn babies in N.S.W. were obtained from the Commonwealth Bureau of Statistics (Commonwealth Bureau of Statistics, 1978, personal communication).

There was no case of parental consanguinity in these families, nor was there any consanguinity

*Details of individual cases are available from authors on request.

known among either the maternal or paternal grandparents. One child was adopted, and this information was not known in this case. Among the siblings of the propositi, there were 13 early 1st trimester spontaneous abortions (in 9 of these families), 89 pregnancies proceeded to term. Given that 15% of all pregnancies abort, these findings indicate that there is no increased abortion rate among cystinuric heterozygotes. There were also 3 stillbirths and one case of premature labour of twins, neither of whom survived. Altogether, fetal loss in these families was not excessive.

Information about relatives with kidney stones was sought but it became clear during history taking that these data were inconsistent from family to family. Many relatives were reported to have had 'kidney trouble', but it was not always possible to verify the information. Only confirmed episodes of calculi among the parents and maternal or paternal grandparents are given, and hence this is a low estimate of the occurrence of renal calculi among relatives of the propositi. These data are shown in Table 3. These 14 relatives were tested and amino-acids were normal in 12 of them, where the calculi were clearly noncystine in composition. One paternal grandfather was a type II heterozygote cystinuric, and one maternal grandmother was a type III heterozygote. Stone analysis was not performed in either of these, but it would seem unlikely that the maternal grandmother had had cystine stones but possible that the paternal grandfather's stones contained cystine. In addition 2 of the fathers had each had a nephrectomy for congenital anomalies of the kidney.

Intellectual achievement of the patients was satisfactory. School progress is reported where at least 2 full years of schooling have been completed at last follow-up. This applied to 35 of the children, and of these, 14 were in the highest class for their age, 16 were in the middle for their age and considered average, and 5 were in the lowest class for their age. In this group of 5 slower children, one boy who was repeating his 3rd year of school was an only child, 2 boys had unaffected siblings considered to be average, one girl had 2 unaffected siblings also in the lowest class for their age, and one girl had an unaffected younger brother who had not yet started school. Of the 14 children in the highest class for their age, 3 were at the top and had excellent reports. One of these is the adopted girl, one girl was ahead of her two heterozygote siblings, and one boy, who had attended a special opportunity class for intelligent children in his area, was advanced compared with his homozygote brother and his 2 other unaffected siblings, who were all in the average class. Only 2 patients have completed their schooling, each was an elder sibling of a propositus. Both were average pupils at school, one is now an office worker and the other a student nurse.

The remaining 26 children include the babies, toddlers, preschool children and those who had not completed 2 full years of schooling. Developmental progress as assessed by milestones was entirely normal in 25 of these children. One child (Case 31) is mentally retarded in the mild to moderate range.

*Two required nephrectomies; one was a heterozygote type II cystinuric, the propositus coming from a mixed family I–II/III.

Discussion

Cystinuria is a disorder of the transport of cystine and the dibasic amino-acids in both the renal tubule and the intestine. The presence of markedly high levels of cystine, lysine, and arginine in the urine of our patients, often with cystine crystalluria, clearly classified them as homozygotes. No intestinal absorption studies were undertaken. It is not always possible in the initial tests to distinguish homozygotes from heterozygotes. In 4 of our patients the classical aminoaciduria was not found in the first two screening tests and appeared in the third and subsequent test. A definitive diagnosis in these children was delayed until their third test had been performed. Similar problems were encountered by Levy *et al.* (1972) who also found repeat testing necessary in some cases; their urine screening programme was the most comparable to our own. The programme in Wales (Bradley, 1975) was similar in structure, but cystine was detected by the nitroprusside spot test initially. We found the nitroprusside test to be very accurate for detecting cystine in the urine, but false-positives and false-negatives may occur (Smith, 1977).

The incidence of cystinuria, based on routine screening of urine from normal infants, has recently been reported by Thalhammer (1975) as part of a collaborative study from 6 centres; Levy reported an incidence of one in 15 841 in Massachusetts, Thalhammer one in 1100 in Vienna, Hyanek in Prague found one in 22 065, Scriver in Montreal found one in 14 084, while in N.S.W. we reported an incidence of one in 5069. On reviewing our data, it was apparent that some cases of type II heterozygotes were included. With these cases eliminated and using an extended population sample, the incidence in N.S.W. has been reduced to one in 17 286. This figure is very similar to the incidence reported by Levy, but is still quite different from those found by Thalhammer (one in 1100), Hyanek (one in 22 065), and Bradley (1975) (one in 27 059 cases). These various figures may reflect true differences in the incidence of homozygous cystinuria throughout the world, or they may be the result of other methods used to detect cases or different criteria for the diagnosis of homozygous cystinuria.

Colliss *et al.* (1963) reported on the stature of 44 patients with cystinuria, 42 of whom had had renal calculus disease. The mean height, adjusted to the adult male population, was found to be 2·5 cm less than that of controls. Our data indicate that homozygous cystinuric children are not smaller than normal children. The height of the cystinuric children was below that expected using the midparent height centiles (Tanner *et al.*, 1970) in only 4 children, but 3 of these were nevertheless on the same height centiles as their unaffected siblings. In one case the propositus was an only child. The parents' heights were generally measured when the patients were seen, in some cases the father's height was reported by the mother.

The birth length data presented here, although incomplete, suggest that affected children do not begin life shorter than normal children. It may be that the shorter stature noted by Colliss is the result of renal calculus disease, as most of her patients had renal calculi; however, our 2 patients with calculi, a 17-year-old and a 4-year-old boy, were both on the 75th centile for height.

Scriver *et al.* (1970) suggested that defective brain transport mechanisms in cystinuric patients may lead to mental retardation. No patient in our group could be considered to be mentally retarded due to cystinuria. One boy was retarded but, as he had other handicaps and congenital deafness, it would not seem justifiable to consider that the retardation was due to cystinuria. Excluding this patient, the intellectual achievement of 35 children who had completed at least 2 years of schooling showed a wide scatter with only 5 being in the lowest class for their ages; they were, however, certainly not retarded. Of the remaining children, the milestones were all adequate and comparable with unaffected siblings, although 10 children born in 1977 were still too young to assess this accurately. Formal psychometry was not performed. Gold *et al.* (1977) did use psychometry on 26 patients in Canada and the intelligence levels of their patients were no different from those of their unaffected siblings or the normal population.

If mental retardation affects 1·5% of the population and the incidence of homozygous cystinuria is one in 15 000, then the chance of both conditions occurring coincidentally would be one in 1 000 000, or 5 people in N.S.W. As noted, only one such child was found.

The general health of these children was good and was in no way impaired by also having homozygous cystinuria. A possible exception is the finding of 2 cases of pyloric stenosis, but further studies will be required to prove if an association exists between the two conditions. Considering the number of patients and the length of time of follow up, there were very few renal symptoms. There were only 2 proved episodes of calculus formation, one episode of renal pain for which no cause was found, and 2 cases of urinary tract infection. This study suggests that renal symptoms in children with cystinuria are rare. The management of all these children consisted of increased fluid intake to the limit of tolerance. It would be satisfying to think that follow-up of the patients and encouragement to maintain increased fluids was the reason for lack of renal symptoms but, in fact, it was difficult to know in most cases what the child's fluid intake actually was, and fluid intake appeared to fluctuate from time to time. Without a control group and stringent control of fluid intake, this aspect of management cannot be adequately assessed.

Among this group of homozygote cystinurics, 60% of the informative cases were of type I inheritance, and 35% were mixed or compound types (Table 2). Bostrom and Hambraeus (1964), in their extensive survey of cystinuria in Sweden, showed that of 59 families studied, 10 contained demonstrable heterozygotes (which they called semicystinuria), giving 83% type I families. Out of 21 families studied by Harris and Warren (1953), 6 contained demonstrable heterozygotes, leaving 71% type I cystinurics (which they named completely recessive); Rosenberg *et al.* (1966) studied 15 patients and found 60% to be type I. The frequency of the different genetic types of cystinuria appears to vary with different populations, although in every large study, the completely recessive or type I form is the most common. This applies to all those studies where the propositi have been mainly stone-forming patients, and also to our study where the patients were detected in an unselected way by urinary screening. It appears, therefore, that the genetic type of the patient is not an important factor for cystine stone formation in a patient with homozygous cystinuria.

We found 14 relatives who had had renal calculi among 270 parents and grandparents (Table 3);

accurate figures for the incidence of renal calculi in this population are not available, but using the annual incidence of Malek (1977) of one in 1000 of the population in the USA, it does appear that our findings show an increase of noncystine stone formation among the relatives of cystinurics.

We thank Elizabeth McKenzie for help in compiling the data and Beryl Morris for typing the manuscript. The late Brian Turner first took an interest in urinary screening for cystinuria and encouraged us to continue follow-up of patients detected.

Diagnostic considerations in ataxia-telangiectasia

JANINE M. JASON AND ERWIN W. GELFAND

Department of Immunology, Research Institute, Hospital for Sick Children, Toronto

SUMMARY 13 children with ataxia-telangiectasia were followed for 6 years. Unlike previously reported cases, these patients had progressive, debilitating neurological disease and slight pulmonary or infectious symptoms. Immunological dysfunction was variable and endocrinological defects were absent. Oculomotor findings, α-fetoprotein levels, and the incidence of chromosomal breakage were the most consistent parameters in the diagnosis of the condition. This disease should be considered in any patient with chronic ataxia, regardless of immunological findings or whether he has a history of infections.

Boder and Sedgwick (1957) presented the first thorough review of ataxia-telangiectasia (A-T) and stressed the prevalence of sinopulmonary symptoms. The incidence of pulmonary complications was considered sufficiently significant to include them as part of the syndrome—ataxia, oculocutaneous telangiectasia, and recurrent sinopulmonary infections. Since then, reports have shown that sinopulmonary infections occur in 45 to 81% of cases (Boder and Sedgwick, 1958, 1963; Peterson *et al.*, 1964; McFarlin *et al.*, 1972; Polmar *et al.*, 1972). Search for the possible cause or causes of this increased incidence of infection in A-T led to a series of articles describing a variety of immunological abnormalities including lymphopenia, decreased lymphoid tissue (Eisen *et al.*, 1965), significant deficiency or absence of IgA (Fireman *et al.*, 1964; Eisen *et al.*, 1965; Epstein *et al.*, 1966; McFarlin *et al.*, 1972; Polmar *et al.*, 1972; Kiran *et al.*, 1974), IgE deficiency (Ammann *et al.*, 1969; McFarlin *et al.*, 1972; Polmar *et al.*, 1972), presence of low molecular weight IgM (McFarlin *et al.*, 1972), decreased delayed hypersensitivity reactions (Eisen *et al.*, 1965; Epstein *et al.*, 1966), decreased E-rosetting and PHA responses (McFarlin and Oppenheim, 1969; McFarlin *et al.*, 1972; Kiran *et al.*, 1974), and variable failure of thymic development (Peterson *et al.*, 1964; Eisen *et al.*, 1965; McFarlin *et al.*, 1972). Unfortunately, there has been no direct correlation between the incidence of any of these defects and the occurrence of sinopulmonary problems.

We were able to evaluate and follow up 13 patients with A-T. These patients differ significantly from those already described. The incidence of sinopulmonary infections was significantly lower and the extent of immunological defects much less severe. We describe the results of our evaluation and emphasise the heterogeneity of this disorder and the difficulties in diagnosis.

Materials and methods

Patients. All 13 patients were children seen at this hospital between 1972 and 1978. They were diagnosed as having A-T by meeting criteria of progressive cerebellar ataxia associated with eye movements simulating ophthalmoplegia, progressive oculocutaneous telangiectasia, and frequently, familial incidence. The population includes three sibships of two siblings in each.

Immunological testing

In vivo

Intradermal skin testing was done as previously described (Gelfand *et al.*, 1972), using *Candida albicans* extract, dermatophyton, diphtheria-tetanus, and streptokinase-streptodornase. A skin test was considered positive if >10 mm induration could be seen after 48 hours.

In vitro

Immunoelectrophoresis was carried out by microtechnique, and quantitative immunoglobulins by radial immunodiffusion. IgE levels were done by radioimmunoassay (Phadebas: Pharmacia, Montreal, Quebec). E-rosettes were determined by a modification of the method of Wybran *et al.* (1972).

Department of Pathology, Yale University, USA
JANINE M. JASON, clinical fellow of immunology
Department of Immunology, Research Institute, Hospital for Sick Children, Toronto
ERWIN W. GELFAND, professor of pediatrics

Lymphocyte transformation assays were performed as previously described (Gelfand *et al.*, 1972).

Nonimmunological testing. Autoantibodies were sought by indirect immunofluorescence to nuclear factors, DNA, mitochondria, smooth muscle, thyroid, and glomerular basement membrane.

α-Fetoprotein levels were carried out by Dr T. Waldmann, NIH, Bethesda, Md, using a radioimmunoassay technique (Waldmann and McIntire, 1972). Chromosome studies were done on peripheral blood lymphocytes.

Results

Clinical data. Table 1 shows that all patients had pronounced ataxia and oculocutaneous telangiectasia. Neurological symptoms were generally noted in the first 2 years of life, but in one patient these were first seen as late as 5 years. Disease was present in 3 sibships; parents were consanguineous in one case. Most significantly, sinopulmonary symptoms were absent or were slight in all 13 patients.

Antibody-mediated immunity (Table 2). Four out of 12 patients had a selective absence of IgA. Low molecular weight IgM was not detected on immunoelectrophoresis and absolute serum IgM levels were normal for age. IgE was present in normal amounts on repeated evaluation in all 11 patients tested. Functional evaluation showed a negative Schick test in 8/8 patients, indicating the presence of neutralising antibodies. One patient converted from a positive reaction after reimmunisation. Isohaemagglutinins were present in all patients. DPT-P booster injections were given to 7 patients, all of whom had significant increases in titres to these antigens.

Cell-mediated immunity (Table 3). Severe and persistent lymphopenia was present in one patient, moderate lymphopenia ($<1\cdot5 \times 10^9$/l lymphocytes) in 3 patients. Delayed hypersensitivity skin testing was positive to at least one antigen in 9/11 patients tested, equivocal in one (about 5 mm induration), and absent in one. E-rosettes were normal in 9/11 patients and slightly decreased in 2/11. PHA response was normal or only slightly decreased in 10/11 cases.

Nonimmunological data. One or more autoantibodies were weakly to strongly positive in 8/11 patients. Most significantly, α-fetoprotein levels were raised in

†Normal = <6% of cells with breaks.

11/11 cases. In one patient the level (44 ng/ml) was just outside the normal range (Waldmann and McIntire, 1972) (Table 4).

Chromosome breakage was present in 8/9 cases. Chromosome-7 was affected in 2 patients and chromosome-14 in 4. D-group involvement was present in 7 patients. Clonal expansion of aberrant chromosomes was noted in 3 cases (Table 5).

So far malignancy has occurred in only one patient (Case 6), who developed acute lymphoblastic leukaemia. Prolonged glucose tolerance tests were normal in all 7 patients tested. Electrolytes, thyroid function studies, and pituitary hormone levels (FSH, LH, growth hormone) were also normal in these patients.

Discussion

Since the complex of progressive cerebellar ataxia associated with bulboconjunctival telangiectasia was first reported in 1926, the multisystem nature of this disease has become clearer (Peterson *et al.*, 1964; Ammann *et al.*, 1970; Paterson *et al.*, 1976). It is now known that involvement may include hepatic and endocrine organs, as well as neurological and immunological systems. The presence of debilitating sinopulmonary disease has been reported as a significant element of this syndrome (Boder and Sedgwick, 1957, 1958, 1963; Peterson *et al.*, 1964; McFarlin *et al.*, 1972). Correlations between pulmonary dysfunction and immunological abnormalities have been looked for without success (Boder and Sedgwick, 1963; Peterson *et al.*, 1964; Eisen *et al.*, 1965; Rosenthal *et al.*, 1965; Ammann *et al.*, 1969, McFarlin *et al.*, 1972).

Our patient population was distinctly different from those reported in the past in that the incidence of sinopulmonary disease was virtually nil. Several possible reasons for this difference may be considered. Firstly, it is possible that we have a genetically isolated population differing from others with this disease. This is unlikely, as our patients came from varied ethnic groups and from different parts of Canada. The second and most likely possibility is that with increased awareness of this disease entity, less severe cases of A-T are now being diagnosed.

Immunological evaluation of our patients has shown similarly minimal dysfunction. IgA deficiency was present in 4/12 (33%) patients, a figure somewhat below those previously reported (Fireman *et al.*, 1964; Eisen *et al.*, 1965; Ammann *et al.*, 1969; McFarlin *et al.*, 1972; Polmar *et al.*, 1972; Kiran *et al.*, 1974). Interestingly, in one of our families, IgA deficiency was present in one patient and not the other, suggesting that the defect in this disease may not reflect a single gene phenomenon, or at least all deficits are not expressed in a simple recessive genetic fashion. IgE levels were found to be within the normal range in all patients. This is at variance with other reports of A-T (Epstein *et al.*, 1966; McFarlin *et al.*, 1972; Polmar *et al.*, 1972). Overall antibody function appeared to be adequate in these patients, as shown by a negative response to the Schick test, the presence of isohaemagglutinins, and a normal booster response to antigen challenge. Similarly, T-cell function was grossly intact in these patients as suggested by delayed-hypersensitivity reactivity, E-rosette formation, and mitogen-induced lymphocyte proliferation. Significant lymphopenia was observed in only one patient. We could find no correlation between an immune defect and sinopulmonary disease in our patients. Specifically, the 4 patients with most noticeable pulmonary symptoms had normal IgA and IgE levels, and lymphocyte counts. Delayed hypersensitivity reactions were absent in one of these patients, percentages of E-rosette forming T-cells were normal or only slightly decreased in all 4. The PHA response was within 1 SD of the mean for normal controls for 3 of these 4 individuals.

Levels of α-fetoprotein were raised in all these patients. This finding, first reported by Waldmann and McIntire (1972), may well become an invaluable diagnostic tool when the diagnosis of A-T is uncertain. Chromosome breakage was extensive in these patients, being present in 8/9 of our patients in whom an adequate number of cells could be obtained for examination. These breaks were of no specific type or unique pattern, although as in other reports (Cohen *et al.*, 1973; Hecht *et al.*, 1973; Nelson *et al.*, 1975), there was a high incidence of group-D involvement.

These findings suggest that the diagnosis of A-T should be considered in patients with moderate to severe neurological symptoms and less obvious involvement of cutaneous or pulmonary systems. We have found the pseudo-ophthalmoplegia in these patients a consistent finding and a useful aid in the diagnosis. α-Fetoprotein levels and evaluation for chromosome breakage have also proved to be valuable diagnostic aids in evaluating equivocal cases of this syndrome. With further awareness of the full range of expression of A-T, more cases without a history of infections and with normal immunological findings will be recognised.

We are indebted to Dr R. Worton, Department of Genetics, for his valuable help. The work was supported in part from a grant from the Medical Research Council of Canada (MT-4875).

Exchange transfusion in newborn infants: effects on granulocyte function

B. PELET

Service de Pédiatrie, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland

SUMMARY During 23 exchange transfusions, the granulocytes from 27 donors and 16 newborn infants were tested for opsonic activity and granulocyte function by the nitrobluetetrazolium test. Granulocyte function in a newborn baby receiving an exchange transfusion can be altered positively or negatively, depending on the quality of the donor's blood. If exchange transfusion is used in the management of neonatal sepsis, special attention should be given to the immunological properties of the donor blood.

Studies have shown the sometimes strikingly beneficial results from blood exchange transfusion (ET) in neonatal septicaemia with sclerema (Prod'hom *et al.*, 1974; Torrado *et al.*, 1974; Xanthou *et al.*, 1975). These results have been attributed to various mechanisms—such as the mobilisation of bone marrow leucocytes (Xanthou *et al.*, 1973), or a rise in serum opsonic activity (Davis *et al.*, 1971). We tested granulocyte function by the nitrobluetetrazolium (NBT) test (Rubinstein and Pelet, 1973), and opsonic activity (Soothill and Harvey, 1976), before, during, and immediately after ET.

IS = Infective syndrome, newborns with clinical features suggesting infection, but no infection documented, HMD = hyaline membrane disease.

Service de Pédiatrie, Centre Hospitalier Universitaire Vaudois, Lausanne

B. PELET, chief resident in paediatrics

Patients and methods

16 preterm and term babies had 23 ETs with 180 ml/kg fresh (<60 hours old) citrated blood (Table). In all of the severely ill newborn babies (Cases 1–8), ET followed earlier transfusions and was combined with chemotherapy (gentamicin, ampicillin, and cloxacillin). Blood samples were obtained from the donor before ET, and then from the baby at the beginning, at one-third and at two-thirds of the ET volume, and at the end of ET.

Leucocytes were isolated from heparinised blood on a Dextran 500 (Urografin) density gradient according to Böyum (1968). NBT reduction was tested, as previously described (Rubinstein and Pelet, 1973), for spontaneous and maximum capacity after stimulation with antigen-antibody complexes (normal human serum and sheep antitotal human serum, Behring). The opsonisation index was determined for the infant's and the donor's serum (2·5%), using the method of Soothill and Harvey (1976). Leucocytes were incubated in the presence of serum with yeast particles for 30 minutes at 37°C. After low-speed centrifugation, one drop of the pellet was dried on a slide and stained with May-Grünewald-Giemsa. The greatest number of yeast particles per granulocytes was 8. As the aim of this study was to find out the effect of ET on granulocyte function, each newborn baby was classified according to the degree of his granulocytic dysfunction and that of the donor.

Statistical analysis used Student's *t* test.

Results

Opsonisation index. This was 4·88 ± 0·26 in 25 of the 27 donors. In the remaining 2 donors (Cases 7 and 9) it was extremely low (<1) and only in ET with blood from them was there a decline in the opsonic activity of the baby's blood (from 6·3 and 4·5, to 0·7 and 1·7). In 15 ETs the index was initially similar in blood from the donor and patient and no change occurred after ET (4·56 ± 0·31, to 4·62 ± 0·31). In 5 ETs in 5 patients (Cases 2a, 3a, 5, 8b, 16) a low opsonisation index was improved by ET with donor blood of a normal index (Fig. 1).

Granulocytes from 9 patients were tested for uptake of yeast particles in autologous and donor sera (Fig. 2). In 11 ETs both sera gave identical results. In 4 ETs in 4 children (Cases 2a, 3a, 8b, 16) there was a significantly lower opsonisation index when the infant's leucocytes were tested in autologous serum compared with donor's serum. This difference disappeared during ET. In 2 patients a lower opsonisation index was observed in the donor's

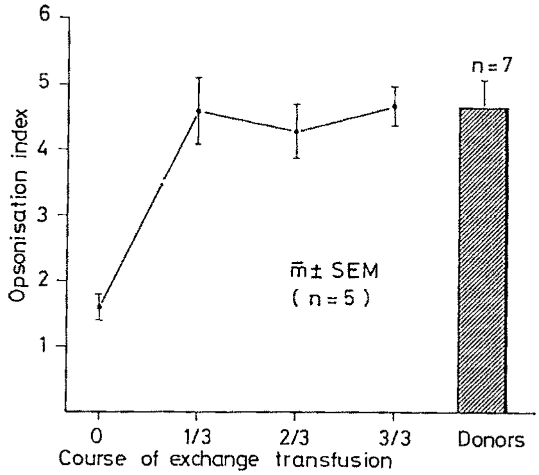

Fig. 1 *Opsonisation test; infants deficient for yeast opsonisation transfused with donor blood with normal yeast opsonisation.*

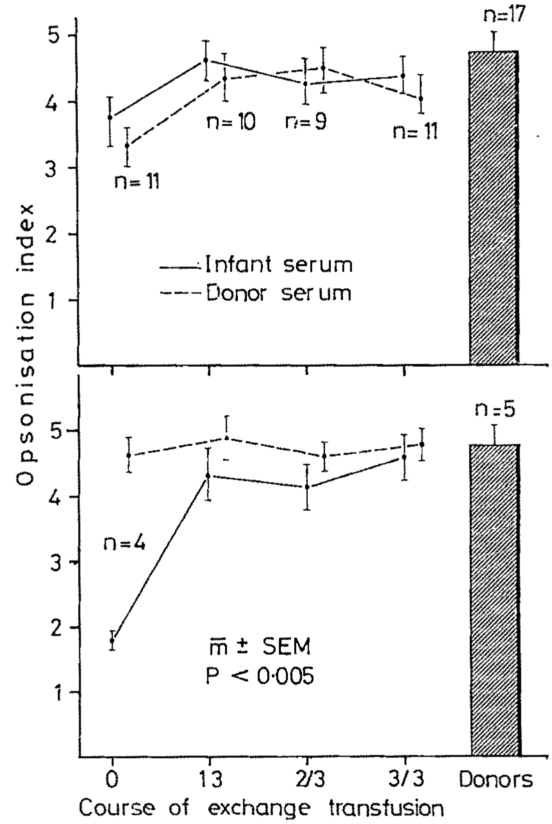

Fig. 2 *Opsonisation test performed on the sera from the baby and donor.*

serum compared with autologous serum. This, however, did not affect the opsonisation index after ET.

Spontaneous NBT reductive activity. Granulocytes showed a wide scatter, as was reported by Moro (1976). In one patient (Case 2) with septicaemia and sclerema, an initial ET with blood containing granulocytes with a low maximum NBT reductive capacity caused no change in the infant's granulocyte spontaneous reduction, while ET with granulocytes of a high maximum NBT reductive capacity improved the infant's granulocyte spontaneous function (Fig. 3).

Maximum NBT reductive capacity. Granulocytes were tested in donor blood and in every baby except one (Case 1). Granulocytes from 13 (52%) donors exhibited normal values (89 ± 2·6%), 8 (32%) donors had moderately decreased values (66 ± 5·6%), and 3 (16%) donors had a much depressed NBT reductive capacity (26 ± 6%). If the donor's granulocytes were normal or slightly depressed for this parameter, no change in the NBT reductive capacity was detected in the infant's blood (Fig. 4). In 3 children with normal maximum reductive activity (Cases 2a, 6, 7), ET with granulocytes of low maximum NBT reductive capacity resulted in a decrease for this parameter in infant's blood obtained at the end of ET. Three babies (4 ETs) (Cases 2e, 3a, 3b, 10) who initially had very depressed NBT reductive capacities received granulocytes with normal reductive capacities and by the end of the ETs, the NBT reductive capacity was normal in all 3 patients (Fig. 5).

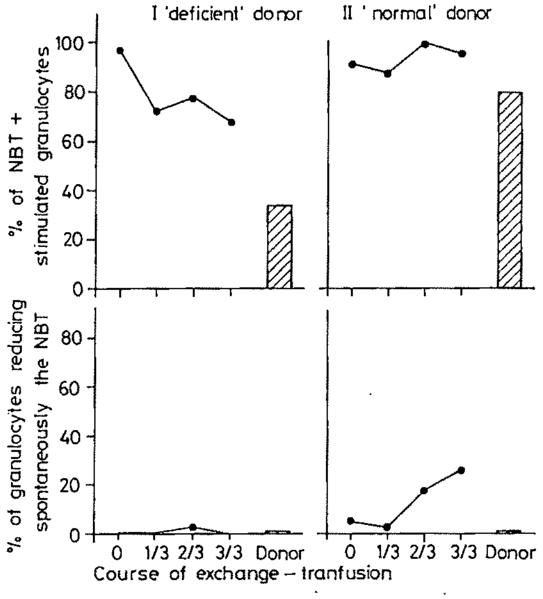

Fig. 3 *(Cases 2a and b) Infants' granulocyte spontaneous and maximum reductive capacity of NBT during exchange transfusion; a preterm baby with* Escherichia coli *septicaemia and sclerema receiving initially a 'deficient', then a 'normal' donor.*

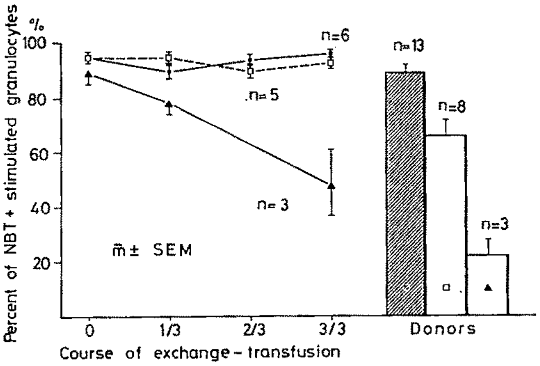

Fig. 4 *NBT test; 'normal' infants transfused with 'normal' or 'deficient' donors.*

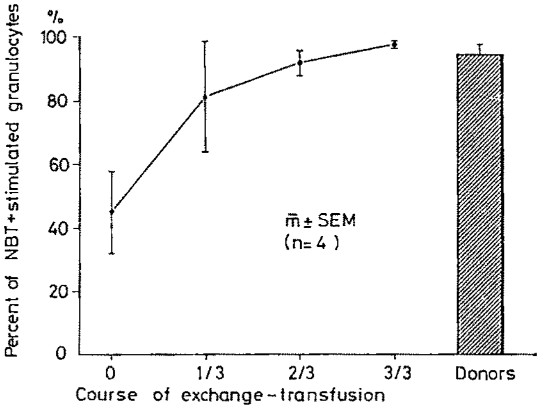

Fig. 5 *NBT test; 'deficient' infants transfused with 'normal' donors.*

Discussion

Our aim was to determine the effects of exchange transfusion on the opsonic activity and granulocyte function of the newborn. Many abnormal immunological functions have been reported in healthy term and preterm babies, including decreased serum opsonic activity, low granulocyte NBT reductive capacity, and altered cell membrane stability (McCracken and Eichenwald, 1971; Stossel *et al.*, 1973; Miller, 1975). But, as suggested by Soothill and

Harvey (1976), we should consider the possibility that decreased opsonisation may be a congenital deficiency. Although the family of neither the baby nor the donor was studied, nor were 'deficient' recipients or donors further studied, an 18-months' follow-up of all newborns affected by septicaemia or other infective illnesses, led to no instance in which such congenital deficiency was suspected.

These data indicate that ET may improve such *in vitro* functions and may possibly modify the poor prognosis of infected infants. We have shown that donor ET blood with normal opsonisation for yeast, and/or donor granulocytes with normal maximum NBT reductive capacity, tended to improve the corresponding function in the newborn baby's circulation. On the other hand, the use of donor blood which was deficient in these functions impaired the opsonic activity and/or the NBT reductive capacity of the recipient. Theoretically, the decrease in opsonins after ET could be due to the dilution of patient's serum with donor serum of low opsonic activity. The effects of ET on granulocyte function may be related to a different mechanism, since transfused granulocytes generally rapidly disappear from the circulation of the recipient, possibly due to clearance (in a positive case) or transfusion (in a negative one) of an inhibitor. It is possible, however, that their retention in the circulation of the newborn is prolonged.

If ET is used in the management of neonatal sepsis, special attention must be given to the immunological properties of such blood. The transfusion of blood with inadequate opsonic activity may prove to be detrimental as judged by a consequential diminution in the recipient's circulation.

A surprising finding was that half the samples of donor blood exhibited an abnormal opsonic and/or NBT reductive capacity of polymorphonuclear leucocytes. The most likely cause is that blood had been stored and then been incorrectly handled (McCullough *et al.*, 1974). As it is impracticable to screen every blood sample for its granulocyte and opsonic function, fresh blood which has been stored at 4°C for no longer than 12 hours should be used.

The clinical importance of correcting these immunological functions by means of ET has yet to be determined on a larger scale. Our initial studies show that the course of neonatal sepsis with sclerema neonatorum may be altered by ET.

We thank Professor D. Danks (Melbourne) and Professor A. Rubinstein (New York) for reviewing the manuscript, and Miss A. Vienny for technical assistance.

Familial hypobetalipoproteinaemia in 9 children diagnosed as the result of cord blood screening for hypolipoproteinaemia in 10 000 Danish newborns

G. E. ANDERSEN, K. BROKHATTINGEN, AND P. LOUS

Neonatal Department, Rigshospitalet, and the Department of Clinical Chemistry, Bispebjerg Hospital, Copenhagen

SUMMARY Out of 10 440 children, 266 with low (<2·5 centile) values for very low-low density lipoproteins in cord serum were chosen to be followed up to find out how many came from families with familial hypobetalipoproteinaemia (FHBL). In 176 families (66% of 266 families), FHBL was diagnosed in 9 children and their families.

Familial hypobetalipoproteinaemia (FHBL) is a genetic disorder which differs from classical abetalipoproteinaemia (ABL) by the presence in the serum of abnormally low, immunochemically identifiable, low density lipoproteins (LDL) in the propositus and in at least one first-degree relative (with no disease to which hypobetalipoproteinaemia could be secondary). An autosomal dominant mode of inheritance is likely (Herbert *et al.*, 1978). FHBL has been described in homozygous and heterzygous forms (Cottrill *et al.*, 1974). Homozygotes are biochemically indistinguishable from patients with ABL having no apolipoprotein B (apo B) or LDL, but they lack the severe neuromuscular degeneration typical of ABL (Salt *et al.*, 1960; Cottrill *et al.*, 1974; Biemer and McCammon, 1975; Muller and Lloyd, 1977; Herbert *et al.*, 1978).

The heterozygous condition is normally asymptomatic; there are however data which suggest that the low serum LDL-C levels may defer the development of coronary heart disease (CHD), thus prolonging life expectancy (Glueck *et al.*, 1976a). This makes FHBL of interest in regard to CHD prevention. So far only two children have been reported born with low levels of total cholesterol (T-C) and LDL-C who were found to have FHBL (Glueck *et al.*, 1976b; Stein, 1977). We describe 9 more such children.

Patients

In our screening programme for hyper- and hypolipoproteinaemia, cord blood was obtained from 10 440 infants (Andersen and Gry Nielsen, 1976). 266 (2·5%) of the 10 440 infants with the lowest VLDL-LDL values were chosen to find out whether they came from families with FHBL.

176 (66%) of the 266 families joined the study after informed consent. Venous blood samples were taken from all 176 fathers and 176 mothers after a 12-hour fast and at least 3 months after birth of their children. Serum lipid and lipoprotein values were determined for each, and if serum T-C was found to be below the sex- and age-adjusted 5th centile value for normal Danes (Andersen and Friis-Hansen, 1976), they were estimated at least three times more, and all other members of the family were invited to join the study so that their serum lipids and lipoproteins could also be determined. In the children <2 years venous blood was taken after an 8-hour fast, in the children >2 years it was taken after a 10- to 12-hour fast.

Methods

Cord serum VLDL-LDL was measured by a modification of the $CaCl_2$-heparin turbidimetric method

Abbreviations:

FHBL:	Familial hypobetalipoproteinaemia

of Burstein and Samaille (1959), on a Greiner Selective Analyser II using 20 µl serum and 1000 µl $CaCl_2$-heparin-precipitation solution. After 5 minutes at 37°C the sample was read at 578 nm against a sample blank. Concentration of VLDL-LDL was expressed in arbitrary units corresponding to the extinction. A frozen (−20°C) stock solution of pooled cord serum (VLDL-LDL concentration: 45 arbitrary units) was thawed and included in over 100 runs. Coefficient of variation was 1·6%, T-C was measured enzymatically on a Greiner Selective Analyser II as described by Borner and Klose (1977). Two cholesterol standards (K-77 and Pathonorm) were included in over 250 separate runs; coefficients of variation were 3·1 and 4·0% respectively. VLDL-LDL-C was measured manually after $CaCl_2$-heparin-precipitation in duplicate (Andersen and Gry Nielsen, 1976). VLDL-C was measured manually in duplicate after ultracentrifugation in a 40·3 rotor, Beckman type L ultracentrifuge at 10°C at 40 000 rev/min for 20 hours. Tubes were sliced. HDL-C values were calculated as the difference between T-C and VLDL-LDL-C.

Serum TG was measured manually in duplicate using the enzymatic method of Eggstein and Kreutz (1966). Two Liponorm triglyceride standards were included in over 100 separate runs. Coefficient of variation was 3·6% (for the 0·42 mmol/l triglyceride Liponorm) and 2·0% (for the 2·50 mmol/l triglyceride Liponorm). Nonparametric statistics (Siegel, 1956) were used.

Results

The serum lipid and lipoprotein values were analysed in the first 200 parents who joined the study. Eight of these 200 parents had serum T-C below the sex- and age-adjusted 5th centile value for normal Danes (Andersen and Friis-Hansen, 1976) and so were assessed for FHBL. Serum lipid- and lipoprotein values in the remaining 192 parents and their 17 children aged 5–19 years are given in Table 1.

Figure *Nine families with hypobetalipoproteinaemia.*

Table 1 also gives the serum lipid- and lipoprotein values in 190 children aged 1–2 years described by Andersen *et al.* (1979a), and in 64 children aged 3–4 years described by Andersen *et al.* (1979b).

FHBL was found in 9 of the 176 families followed up. These 9 families are shown in the Figure, and the corresponding lipid- and lipoprotein values in parent/child pairs are given in Table 2. None of the parents or grandparents had been known to have FHBL before the study.

Discussion

The distribution of serum T-C values in 20- to 29- and 30- to 39-year-old men and women in the study is almost identical with that found earlier in similarly aged Danish fathers and mothers, in whom the 5th centile value for serum T-C was 4·26 and 4·42 mmol/l respectively (Andersen and Friis-Hansen, 1976).

The study did not allow precise calculation of the incidence of FHBL in Danish children, as only 66% of newborn babies with <2·5 centile values for cord serum VLDL-LDL were studied. As out of 10 000 consecutively born infants we found 9 with a three-generation vertical transmission of hypocholesterolaemia, this gives an incidence of at least 0·09%.

Hitherto only two children with FHBL had been reported with low cord serum T-C and/or LDL-C. The child described by Glueck *et al.* (1976b) had a normal cord serum T-C of 1·37 mmol/l and a low LDL-C of 0·23 mmol/l. In the child described by Stein (1977) cord serum T-C was 1·29 mmol/l and LDL-C 0·44 mmol/l. In the present study where only the cord serum VLDL-LDL was determined by the turbidimetric screening method, we show that in newborn babies with low values of cord serum VLDL-LDL, FHBL can be diagnosed at follow-up in at least 0·09% of the children and their families. The condition is therefore by no means a rare inborn error of metabolism.

Lipoprotein measurements—a necessity for precise assessment of risk in children from high-risk families

D. HELDENBERG, I. TAMIR, O. LEVTOW, Y. BURSTEIN, AND B. WERBIN

Paediatric Department Tel-Aviv Medical Centre and Sackler School of Medicine

SUMMARY Serum lipids and lipoproteins were measured in 67 high-risk children, aged between 2 and 17 years, who were the offspring of 33 fathers with hypercholesterolaemia. 18 of the 33 fathers had had a myocardial infarction (MI) before 44 years of age. In 15 of the fathers there was no history of accelerated coronary heart disease (CHD). No difference in the concentrations of the serum lipids and lipoproteins was found between the children whose fathers had a history of MI (n = 31) and the children with no family history of CHD (n = 36). Serum lipids and lipoproteins were also measured in a control group of 19 children, aged between 2 and 17, whose parents were normolipaemic and had no history of atherosclerosis. Serum total cholesterol (TC) and low-density lipoprotein cholesterol (LDLc) concentrations were significantly higher—5·47 ± 1·36 mmol/l (211 ± 52 mg/100 ml) and 3·55 ± 1·16 mmol/l (137 ± 45 mg/100 ml) respectively—in the 67 'high-risk' children than in the control group—TC, 4·46 ± 0·64 mmol/l (172 ± 25 mg/100 ml); LDLc, 2·56 ± 0·64 mmol/l (99 ± 25 mg/100 ml). No statistically significant difference was found in serum triglyceride (TG) or high-density lipoprotein-cholesterol (HDLc) concentrations between these two groups.

In 7 of the high-risk children, raised levels of serum TC >5·74 mmol/l (>221 mg/100 ml) were due to raised HDLc >1·95 mmol/l (>75 mg/100 ml) and normal LDLc <3·84 mmol/l (<148 mg/100 ml). In spite of their increased TC levels these children are probably at a lower risk for CHD as a result of the protective effect of HDL. In 3 children, raised concentrations of LDLc (>3·84 mmol/l) were accompanied by low levels of HDLc (<1·19 mmol/l) and normal concentrations of TC (<5·74 mmol/l). These children are probably at the highest risk for CHD.

The correct diagnosis would have been missed in 10 (15%) of the children had only TC been measured. It is therefore imperative to measure lipoprotein levels in addition to TC in all children from 'high-risk' families, regardless of their TC concentrations.

During the last two decades some risk factors associated with coronary heart disease (CHD) in young adults have been identified. Ways have been found to reduce these risks as a possible means to prevent, or at least delay, CHD (Berenson *et al.*, 1978; Glueck *et al.*, 1978a, b). As many of these risk factors can be identified in childhood, attempts to change relevant behaviour—for example, diet, physical activity, and smoking—may usefully be made at this age.

In adults there is a positive association between CHD and serum total cholesterol (TC) and low-density lipoprotein (LDL) (Kannel *et al.*, 1971; Tyroler *et al.*, 1975; Castelli *et al.*, 1977). More recently, an inverse association between high-density lipoprotein (HDL) and CHD has been established (Tyroler *et al.*, 1975; Glueck *et al.*, 1976; Castelli *et al.*, 1977).

Of the known risk factors for CHD, plasma lipids and lipoproteins are particularly relevant to children because (1) hypercholesterolaemia can be detected at an early age, and (2) dietary modification, combined in severe cases with cholestyramine, can lower the levels of serum cholesterol in children (Segall *et al.*, 1970; West and Lloyd, 1973; Glueck *et al.*, 1978b).

Although screening large groups of children to detect familial hypercholesterolaemia (FH) is unlikely to be profitable (Leonard *et al.*, 1976; Lloyd,

Y. BURSTEIN, instructor in paediatrics
B. WERBIN, associate clinical professor of paediatrics
I. TAMIR, associate professor of paediatrics

1977), efforts should be made to screen children from high-risk families (Leonard *et al.*, 1976). Many children from families with accelerated CHD and hypercholesterolaemia will also have raised plasma lipids (Tamir *et al.*, 1972).

However, recent evidence has suggested that measurement of lipids only may be insufficient to assess the true risk for CHD. For example, Glueck *et al.* (1978a) reported that about 16% of schoolchildren with raised plasma TC levels had normal concentrations of LDL and the increase in TC was due solely to raised plasma HDL. In view of the protective effect of HDL, these children were putatively at a lower risk for CHD, which obviated the need for intervention.

We report on the distribution of serum lipids and lipoproteins in 67 children from 33 high-risk families, and reiterate the need to measure lipoproteins, in addition to TC and triglyceride (TG), for the correct diagnosis of abnormalities in such children.

Patients and methods

67 children (38 boys and 29 girls) aged between 2 and 16 years (mean 8·8) were investigated. They were the offspring of 33 hypercholesterolaemic (that is—serum TC >95th centile) fathers and normolipaemic mothers. Serum TG concentrations in all the fathers were normal. The fathers of 31 children had a history of CHD verified from hospital records (pathognomonic ECG changes and increased serum enzymes), whereas in the fathers of 36 children there was no history of atherosclerosis. All the fathers were less than 44 years old at the time of examination.

For comparative purposes, we also measured serum lipids and lipoproteins in 19 children (mean age 11·6; range 2–17 years) whose parents were normolipaemic and had no history of atherosclerosis.

Blood samples were obtained after an overnight fast (at least 12 hours). Children under 5 years were allowed water until 2 hours before examination. Serum TC was estimated by the method of Rappaport and Eichhorn (1960) and TG by the method of Shafrir and Khassis (1969). Because TG concentrations were <3·25 mmol/ (<298 mg/100 ml) in all samples, HDL-cholesterol (HDLc) was assessed by precipitation of the very low density lipoprotein (VLDL) and LDL with a heparin-manganese chloride solution and measurement of the cholesterol content of the supernatant. VLDL-cholesterol was assumed to be equal to serum TG/2, and LDL-cholesterol (LDLc) was calculated as the quantity: TC-HDLc-VLDLc.

Results

The concentrations of serum lipids and lipoproteins in the three groups of children are shown in Tables 1 and 2. For all the parameters studied, no statistically significant differences were found between the children of fathers without CHD (group 1) and the children of fathers with CHD (group 2). Therefore, these two groups were combined for subsequent analyses. The children from the high-risk families (groups 1 and 2) had significantly higher levels of TC ($P<0\cdot01$), and LDLc ($P<0\cdot001$), than the children in the control group. No significant differences were detected in the concentration of TG or HDLc.

The Figure shows that in 30 (40%) of the high-risk children, TC concentrations exceeded the mean level of the control group by >2 SDs. In three of these, serum TG levels were also raised. One child had normal TC but an increased TG level. Of the 30 children in whom hypercholesterolaemia was present, only 23 had high TC levels resulting from raised LDLc. In 7 children, the TC levels were high but LDLc concentrations were normal. In these 7 children HDLc exceeded the mean of the control

group by 1 SD, and thus was the main contributor to the raised TC levels. In 3 children, raised levels of LDLc (>3·84 mmol/l) were accompanied by low HDLc (<1·19 mmol/l), resulting in normal TC (<5·74 mmol/l).

Discussion

The importance of detecting risk factors for CHD as early as possible in childhood is now well accepted (Glueck *et al.*, 1974; Levy and Rifkind, 1974; Lauer *et al.*, 1975). It is assumed, but not yet confirmed, that instituting measures to correct these risk factors early in childhood will prevent, or at least delay, the onset of atherosclerosis and its main manifestation—CHD.

Raised plasma or serum lipids, mainly TC, are among the main factors that are especially associated with increased risk for CHD in young adults (Kannel *et al.*, 1971; Blackburn, 1974; Keys, 1975; *Lancet*, 1977). Moreover, the risk for developing early atherosclerosis is particularly high in patients with FH, especially in young men (Slack, 1969; Stone *et al.*, 1974). Hence, screening children to detect FH is recommended by some but not all paediatricians (Lloyd, 1975). However, it is generally agreed that children from high-risk families—that is families with a history of accelerated atherosclerosis or hyperlipoproteinaemia—should be examined for detection of FH (Tamir *et al.*, 1972; Glueck *et al.*, 1974; Leonard *et al.*, 1976; Lloyd, 1977).

Diagnosis of FH is usually based on a raised level of TC or LDLc in the propositus and in at least one first-degree relative. However, because about 70% of plasma TC is carried in the LDL, it has been generally accepted that in most instances measurement of TC is sufficient for appropriate diagnosis.

The importance of the inverse relationship of HDLc and CHD has been reported (Tyroler *et al.*, 1975; Glueck *et al.*, 1976; Castelli *et al.*, 1977) and HDL is now considered a 'negative risk factor' for CHD. Measurement of lipoproteins is thus assuming greater importance for proper diagnosis and treatment. In addition to the study by Glueck *et al.* (1978a), in which up to 16% of a group of schoolchildren with raised TC levels had normal LDLc but increased HDLc, it has also been shown that about one-third of children referred because of hypercholesterolaemia had increased concentrations of HDLc with normal LDLc (Neill *et al.*, 1977). Curiously, these children are putatively at a lower risk for CHD, in spite of their raised TC levels.

In 10 (15%) of the 67 children reported here, the correct diagnosis would have been missed if TC and TG alone had been measured. In 7, the increased TC levels were caused by increased concentrations of HDLc (with normal concentrations of LDLc). These children probably have a lower than normal risk for developing CHD; therefore, any measures aimed at reducing their TC are probably not warranted. At the same time, however, the normal TC levels in 3 children were the result of increased LDLc but low HDLc. These children, who are probably at the highest risk for CHD (Kwiterovich, 1977), would also have been missed had only TC been estimated.

Our results confirm earlier reports that approximately 40% of the children born to matings of familial hypercholesterolaemic and normolipaemic parents will have FH (Tamir *et al.*, 1972; Kwiterovich *et al.*, 1974). The need for accurate diagnosis is especially important in the children from these high-risk families; it is likely that they carry the genetic form of hypercholesterolaemia, which has been shown to be associated with a very high risk for CHD.

We advocate measurement of lipoproteins in these children—although it is more complex and requires special skill and equipment—as it clearly enhances diagnostic precision and improves the assessment of their risk. Furthermore, it facilitates appropriate treatment and prognostication. This is important not only for the fortunate children whose raised TC levels result from raised HDLc, who are thus putatively at lower risk for CHD, but it is of vital importance for the children whose normal TC levels (but low HDLc) do not accurately reflect their high-risk status.

Folate nutrition and growth in infancy

Y. MATOTH, I. ZEHAVI, E. TOPPER, AND T. KLEIN

Department of Paediatrics, Beilinson Medical Centre, Petah Tiqva, and the Sackler School of Medicine, Tel Aviv University, Israel

SUMMARY The effect of suboptimal folate nutrition on the growing infant was studied in a population of infants fed a diet based on boiled, pasteurised cows' milk. One group of infants received a daily supplement of 1 mg folic acid from age 2 months, while the other group received a placebo. The infants were seen at bimonthly intervals. In the supplemented group the red cell folate level had increased to twice its pretreatment value by 4 months, and remained at this high level to the end of the first year. Hb concentration and incidence of anaemia were similar in both groups. The incidence of infection in the two groups did not differ. Weights and lengths attained at 6 months, and the rate of gain from 2 to 6 months were higher in infants whose folate levels were above the median value than in those below it. In the second half of the first year the differences between the two groups were no longer evident.

The classical description by Zuelzer and Ogden (1946) of folate-responsive megaloblastic anaemia of infancy drew attention to the fact that young babies were a group particularly at risk for folate deficiency. Interest subsequently focused largely on megaloblastic anaemia as a manifestation of folate deficiency. Other, less obvious effects of suboptimal folate nutrition are less well documented.

The present study was initiated to detect any effects of folate undernutrition on the growing infant. The study was facilitated by the practice of infant feeding current in Israel, which is based on the use of boiled pasteurised cows' milk. Milk treated in this manner has been shown to be a poor source of folate. Furthermore, infants fed such a diet tend to have low blood-folate levels (Matoth *et al.*, 1965). It was therefore of interest to investigate whether a population of apparently healthy infants fed the standard diet and presumed to be suboptimally provided with folate was in any way inferior to a folate-replete group, created by the daily administration of large doses of folic acid.

Study population and methods

The study was carried out in Rosh Ha-Ayin in central Israel. This community was chosen because it is uniformly inhabited by Yemenite Jews who immigrated to Israel in 1949–50 and therefore represent a homogeneous population with respect to ethnic and cultural backgrounds as well as to socioeconomic status. The Rosh Ha-Ayin area is served by two child health clinics. Each infant attending clinic A received a daily supplement of 1 mg folic acid in the form of a specially prepared tablet, while those attending clinic B received a placebo. Supplementation was started at 2 months and the infants were seen at regular bimonthly intervals from age 2 months to one year. The red cell folate levels, Hb concentrations, weights and lengths were determined at each visit. At each clinic the infants were weighed and measured by the same experienced trained nurses. The incidence of infection was monitored and recorded.

100 term infants whose birthweights were >2·5 kg were studied. The male:female ratio was 53:47 in clinic A and 49:51 in clinic B. The attendance was practically complete. It was therefore possible to terminate the study when the first 53 infants in clinic A and the first 60 in clinic B had reached age one year. The mothers did not know which infant was receiving the active material. Each was informed of the potentially beneficial effects of folic acid, and her consent to enrolling the infant in the trial and her co-operation were obtained.

Folate in whole blood was determined with a micromethod using 0·1 ml skin prick blood. The procedure of Cooperman (1967) was followed. The

method has been in routine use in our laboratory for the last 10 years and has given consistent results. The folate values obtained with this method are higher than those recorded in our earlier publications (Matoth *et al.*, 1965). Red cell folate was calculated by multiplying the values found in whole blood by 100 ÷ haematocrit.

Results

Red cell folate values, determined at bimonthly intervals from 2 months to one year of age in the infants supplemented with folate (clinic A) and in the unsupplemented group (clinic B), are shown in Table 1. The initial values, obtained at 2 months before supplementation was begun, were similar in both groups. Thereafter, folate values in babies from clinic B remained low at 4 and 6 months and showed a moderate increase subsequently. In contrast, supplementation with folic acid (clinic A) more than doubled the red cell folate at 4 months, and this high level was maintained throughout the first year.

It can be seen from Table 1 that the increase in folate had no effect on Hb concentration, which remained very similar in the two groups throughout the period of observation. The mean values in both groups tended to decrease in the second half of the first year. This was due to the occurrence of anaemia. 15 infants in clinic A and 11 in clinic B had Hb <10 g/dl when they were between 8 and 12 months; the anaemia was caused by iron deficiency. They were given treatment with iron and excluded from further study.

Of 357 episodes of acute gastroenteritis and respiratory infection recorded during the period of observation, 164 were in babies from clinic A and 193 from those at clinic B. The difference was, however, not significant.

In the group of infants supplemented with folic acid from age 2 months, the weights and lengths attained at 4 and 6 months were significantly higher than in the unsupplemented group. The difference was no longer evident in the second half of the first year (Table 1). The relation of changes in weight and length to the folate status was further evaluated by combining the babies from both clinics and comparing, for each age group, infants whose folate levels were above the median value with those whose

High and low folate = folate levels above and below the median value at 6 months.

levels were below it (Tables 2 and 3). Weights and lengths at 6 months were significantly higher in the high folate than in the low folate group. In the former, weights were higher also at 4 and 8 months. As shown in Table 3, the rate of gain in weight and length from 2 to 6 months, calculated from individual increments, was significantly higher in the high folate group.

Discussion

It is evident from our data that growth can be enhanced in apparently healthy infants by providing them with an abundant supply of folic acid. Conversely, it may be concluded that a shortage of folate can be a limiting factor to growth. This is not surprising, as it is well known that folates are essential for DNA and RNA synthesis. Accordingly, the folate requirements for cell proliferation in the rapidly growing organism are very high. The fetus is well endowed with folate at birth. Soon after, the blood folate level decreases and reaches a low point at 6 to 8 weeks (Matoth *et al.*, 1964a). From that age on the infant depends entirely on diet for its folate needs. The age group 2 to 6 months is, therefore, a critical period. On the one hand, this is a period characterised by a high growth rate and, accordingly, maximal folate requirements. If, on the other hand, intake is marginal, as is the case in our population, shortage of folate may affect growth. In the second half of the first year, as growth slows down, there is a relative decrease in folate requirements. At the same time intake is increased by the introduction of folate-rich foods. As a result, the infants achieve a better folate balance and catch up in weight and length with their folate-replete fellows.

There are few reports dealing with the effects of folate deficiency on growth. The administration of 50 μg folic acid per day to low birthweight infants did not increase their weight at 6 months (Kendall *et al.*, 1974). More recently, Gandy and Jacobson (1977a) found in infants with erythroblastosis fetalis a tendency to low serum-folate, which persisted throughout the first year of life. In these infants there was a strong correlation between low serum-folate and the rate of weight gain. It is of interest that supplements of 2·5–5 mg folic acid given to erythroblastotic infants resulted in an increase in the rate of weight gain at 4 months, compared with non-supplemented erythroblastotic controls (Gandy and Jacobson, 1977b).

In the present study, folate shortage of a degree sufficient to cause a measurable deceleration of growth did not affect Hb concentration. The incidence of anaemia was similar in the folate-rich and folate-poor groups. Anaemia, when present, bore the mark of iron deficiency. Furthermore, it occurred late in the first year, at a time when folate shortage, as shown by its effect on growth, was no longer evident. The high incidence (26 cases) of anaemia in our material reflects the prevalence of iron deficiency in babies in Israel.

In a previous study (Matoth *et al.*, 1964b), hospitalised infants with a wide range of Hb and folate levels showed no correlation between these two variables. It appears therefore that, even in a population of infants with relative shortage of folate, iron deficiency is the dominant factor in nutritional anaemia, whereas folate deficiency of a degree of severity or duration necessary to produce anaemia is uncommon.

Nutritional status of light-for-date infants at birth and its influence on early postnatal growth

D. P. DAVIES, P. PLATTS, J. M. PRITCHARD, AND P. W. WILKINSON

Department of Child Health, Leicester Royal Infirmary Maternity Hospital

SUMMARY The ponderal index (PI) (g/cm^3 × 100) was used to define the state of nutrition at birth of 47 light-for-date (LFD) term infants and to determine how intrauterine undernutrition influences growth during the first 6 months of postnatal life, at four age intervals: birth–4, 5–8, 9–12, 13–26 weeks. With the exception of one baby, each PI was <50th centile on the Miller and Hassanein standards: in 24 (51 %) babies the PI was <3rd centile. This suggests that, generally, LFD infants are underweight for length, and by inference, are likely to have experienced intrauterine undernutrition. In the first month the 24 'wasted' infants (PI <3rd centile) gained more rapidly in weight, and grew more quickly in head circumference and length than the 16 'nonwasted' infants (PI >10th centile). Thereafter growth rates were similar. With the exception of weight in the 'nonwasted' infants during the first month, rates of growth (weight, length, and head circumference) in both groups of babies in each of the 3 months after birth were greater than in normal infants. The first 3 months after birth can therefore be defined as the period of 'catch-up' growth in LFD term infants.

From their outward appearance light-for-date (LFD) infants who show no signs of congenital malformations or intrauterine infection can be differentiated according to the extent to which they show external signs of intrauterine undernutrition. Some show unmistakable features of wasting while others seem to show none, resembling instead 'perfect miniatures'. Little is known about postnatal growth after intrauterine undernutrition as no study of growth in LFD infants (for example Babson, 1970; Fitzhardinge and Steven, 1972; Brandt, 1976; Martell *et al.*, 1978) has paid regard to the state of nutrition at birth. In the present study we used the ponderal index (PI) (Miller and Hassanein, 1971; Jarai *et al.*, 1977) to investigate the nutritional status of LFD infants at birth, and to see how intrauterine undernutrition affects growth during the first 6 months of postnatal life.

Materials and methods

Study infants. 47 consecutively born term infants were studied: all were white and singletons. None had any congenital malformation or any external feature of intrauterine infection. The weight of each infant was <5th centile for gestation, allowing for sex, mother's height, and birth order (Tanner and Thomson, 1970). Weight, length, and head circumference were measured (D.P.D.) between 24 and 48 hours of age, using methods previously described (Davies, 1976). For each infant the PI (g/cm^3 × 100) was calculated and according to the distribution on the centile standards of Miller and Hassanein (1971) two groups of infants were defined:

Group 1, 'wasted'
24 infants whose PIs were <3rd centile for gestation.

Group 2, 'nonwasted'
16 infants whose PIs were >10th centile for gestation.

Seven infants in whom the PI was between the 3rd and 10th centiles were not included in the final analysis.

Evaluation of growth. Measurements of weight, length, and head circumference were made (D.P.D.) at 1, 2, 3, and 6 months (±3 days of the projected date). Individual growth velocities were calculated for 4 age intervals (birth–4, 5–8, 9–12, 13–26 weeks). Mean values were calculated and the statistical significance of any differences was tested by Student's *t* test.

P. W. WILKINSON, consultant paediatrician

As well as comparing growth rates between the two groups of LFD infants, comparisons were made with infants in whom the rate of intrauterine growth had been normal. For this purpose, velocity growth curves for weight, length, and head circumference were constructed from data on 50 term infants of appropriate weights for gestation, who had also been seen at birth, and at 1, 2, 3, and 6 months (P. W. Wilkinson, unpublished observations).

Results

Distribution of PI. Fig. 1 shows the distribution of each PI for the 47 babies according to the Miller and Hassanein standards. All, except one baby, were <50th centile and 24 (51 %) were <3rd centile.

Birth data. Mean values for gestational age, weight, length, head circumference, and PI at birth in both groups of infants are shown in Table 1. Group 1 infants were on average 83 g lighter and 1 cm longer than those in group 2, but the mean values for head circumference were the same.

Growth. Rates of weight gain, length, and head circumference are given in Table 2. Weight, length, and head circumference growth rates were significantly higher ($P<0 \cdot 01$) in group 1 infants during the first month. Thereafter the growth velocities showed no significant differences.

Figs 2–4 show the velocity growth curves for groups 1 and 2 compared with normal infants. Except for weight in the first month in infants in group 2, the mean curves of weight gain, length,

and head circumference growth in infants in both groups were consistently higher than those for normal infants during the first 3 months. At between 3 and 6 months the growth rates in both LFD categories were close to normal.

Discussion

The fact that all but one infant had a PI<50th centile at birth suggests that in general LFD infants are underweight for length and likely therefore to have experienced, to a variable extent, inadequate intrauterine nutrition. This is further supported by the observation that 'nonwasted' as well as 'wasted' infants showed above average growth rates in the first 3 months after birth. Campbell showed by intrauterine biparietal cephalometry that as many as 20 to 30% of LFD infants at birth had symmetrical growth retardation due to reduced fetal growth potential (Campbell, 1974). Our data suggest that the proportion of LFD infants who show symmetrical growth retardation is smaller. Indeed our two groups might have been more appropriately termed 'wasted' and 'not-so-wasted' as there would appear to be a continuum of intrauterine undernutrition from those severely affected to those much less affected.

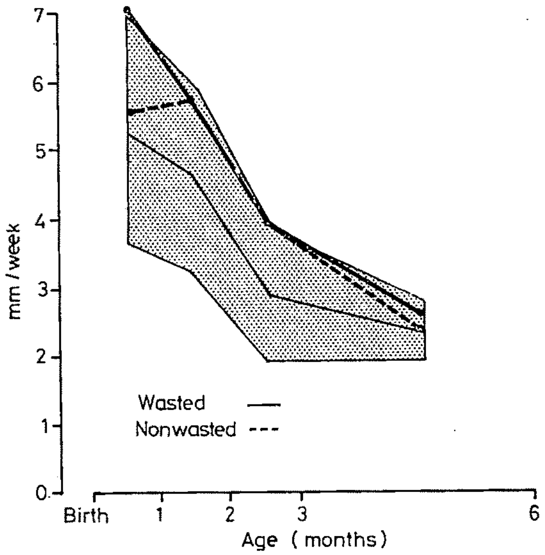

Fig. 4 *Curves of mean head circumference growth velocities in LFD term infants. Shaded area represents the mean ±1 SD head circumference growth velocity of 50 normal term infants.*

In view of the greater than normal growth rates in LFD infants in the first 3 months, this period can be defined as 'the catch-up period'. Furthermore, the fact that during the first month the infants in group 1 grew more rapidly than those in group 2 suggests that much of the intrauterine growth deficit is made up very early in postnatal life. These observations are at variance with Widdowson (1974) who, in a study of the effects of intrauterine undernutrition on postnatal growth in small animals wrote: 'In animals, the rate of growth after birth is related to the size at birth, and the same on the whole is true in man.' Our data show that this is clearly not the case for the newborn human infant who has been underfed in intrauterine life.

We thank the mothers of all the babies who participated in this study, several of our colleagues for criticism, and Mrs F. Quinton and Miss S. Mangal for secretarial assistance.

Non-neuropathic Gaucher disease presenting in infancy

P. HODSON, J. GOLDBLATT, AND P. BEIGHTON

Red Cross War Memorial Children's Hospital, Rondebosch, University of Cape Town, and Groote Schuur Hospital, Cape Town

SUMMARY The non-neuropathic form of Gaucher disease was diagnosed in 11 children of non-Jewish ancestry in South Africa; all were under the age of 4. None had any neurological involvement and, apart from the precocious presentation and rapid course, the features in each resembled those of the classical 'adult' or chronic non-neuropathic form of Gaucher disease. By contrast, the condition presented after puberty in 24 out of 28 Ashkenazi Jews who were studied during the same investigation. Activity of β-glucosidase was defective in both groups of patients and they could not be distinguished by histological criteria. Only one child with the infantile neuropathic form of Gaucher disease was identified during the survey. The preponderance of the atypical non-neuropathic form of the disorder in young children is of practical importance from the point of view of differential diagnosis in any child with hepatosplenomegaly.

Gaucher disease is conventionally classified into three types: the adult or chronic non-neuropathic, the acute neuropathic infantile, and the subacute neuropathic juvenile (Fredrickson and Sloan, 1972).

The adult or chronic non-neuropathic form is characterised by splenomegaly, dyshaemopoeisis, and orthopaedic complications, in the absence of any neurological involvement. This entity has an overwhelming predilection for Ashkenazi Jews and is by far the most common form of Gaucher disease (Matoth and Fried, 1965). In the infantile type cerebrosides accumulate in the brain and death occurs before age 2. The rare, poorly defined juvenile type has onset in later childhood, involvement of the central nervous system, and a subacute course.

In a survey of all forms of Gaucher disease in South Africa in which 46 patients were investigated we found 13 young children with non-neuropathic Gaucher disease. In 11 of these, the disorder was diagnosed by age 4. As this condition usually presents in adulthood, this precocious onset is a matter of considerable clinical importance. A typical case is reported and details of the manifestations in the other affected children are tabulated and discussed in order to arouse diagnostic awareness and to emphasise that the non-neuropathic form of Gaucher disease can occur in infancy.

Patients and methods

Since 1971, attempts have been made to examine and investigate every patient with Gaucher disease in South Africa. So far 46 with the chronic non-neuropathic form have been studied and in each the diagnosis was confirmed histologically or by demonstration of defective leucocyte β-glucosidase activity. Of these patients 28 were Ashkenazi Jews, 10 were Afrikaners, 3 were of mixed ancestry, 2 were African Negroes, and 3 were British. The survey methodology and the findings in the Ashkenazim have been reported elsewhere (Beighton and Sacks, 1974; Myers *et al.*, 1975; Goldblatt *et al.*, 1978). The genetic implications of Gaucher disease in the Afrikaners, including 7 of the patients in the present series, have also been reported (Goldblatt and Beighton, 1979b).

Surprisingly, the so-called 'adult' non-neuropathic form of Gaucher disease was diagnosed before age 4 in 11 patients, and at 6 and 8 years in 2 others. Apart from a pair of siblings in a Sephardic-Ashkenazi family, all these children were Afrikaners or of mixed ancestry. By contrast, the condition was clinically apparent in only 4 of the 28 Ashkenazi Jews before puberty and their symptoms were slight.

P. BEIGHTON, professor of human genetics

The classical infantile neuropathic form of Gaucher disease was found in only one patient, a baby born to a consanguineous Indian couple.

Personal and clinical data on the children with non-neuropathic Gaucher disease are shown in the Table, and a brief case report is given below.

Case report. Case 9, the only child of nonconsanguineous parents of mixed ancestry was born in 1974. He weighed 2·6 kg at birth and his neonatal course was complicated by jaundice, for which he received phototherapy.

He had several episodes of croup and bronchospasm during infancy and, at age 2, hepatosplenomegaly was detected during routine examination. Histological studies of bone marrow were undertaken and the diagnosis of Gaucher disease was established. Up to this point, his developmental milestones had been normal.

He was then lost to follow-up until, at age 3½, he again presented with shortness of breath and pyrexia. At this stage his abdomen was distended by a huge spleen which extended into the right iliac fossa, and the liver projected 10 cm below the inferior costal border (Figure). No abnormality could be detected in his central nervous system.

At this time he was pancytopenic with Hb 6·3 g/dl, a platelet count of $35 \cdot 0 \times 10^9$/l and total WBC of $3 \cdot 4 \times 10^9$/l, of which 8% were polymorphs.

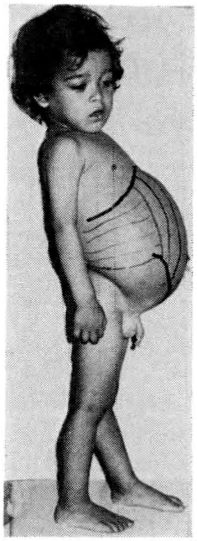

Figure *3-year-old child (Case 9) with Gaucher disease. Massive hepatosplenomegaly is evident.*

During his stay in hospital he had several episodes of massive epistaxis which were attributed to his

thrombocytopenia. Cardiac failure developed after numerous blood transfusions, and treatment with digitalis was eventually needed.

β-Glucosidase activity in cultured fibroblasts obtained after skin biopsy was markedly diminished. His mother had intermediate levels of activity in her own cultured fibroblasts, and this was taken to be indicative of her status as a heterozygote for the Gaucher disease gene. The father was not available for investigation.

The patient is now aged 3¾ years. He experiences considerable malaise and his activity is impaired by the gross distension of his abdomen. He has severe hypersplenism and chronic anaemia with a large heart and borderline cardiac failure. His prognosis is considered to be poor.

Discussion

Although they share a common autosomal recessively inherited defect of the enzyme β-glucosidase (Brady, 1978), it is generally accepted that the infantile, juvenile, and adult or non-neuropathic forms of Gaucher disease are separate conditions. At a clinical level death from central nervous system involvement in the infantile and juvenile types, and the prolonged course and absence of neurological complications in the adult form, represent obvious distinctions between these entities.

The ethnic predilection of the adult form of Gaucher disease for the Ashkenazim is well known and in the Jewish community of South Africa this condition is present in about one in 4000 (Goldblatt and Beighton, 1979a). None of our Ashkenazi Jewish patients with this type of the disorder had any neurological involvement and only 4 experienced symptoms before puberty, and these were slight. By contrast, with the exception of the pair of siblings with an Ashkenazi father and a Sephardic mother, none of the 11 children who developed symptoms before age 4 was Jewish. In these children there were no changes in the central nervous system and, apart from the precocious onset and rapid progression, the disease followed the same general course as in the Jewish patients.

The reason for this temporal discrepancy in the development of the disorder is unknown although at a fundamental genetic level allelism or epistasis could be invoked as possible explanations. In view of the nature of our survey methodology, it is unlikely that ascertainment bias or inadequate case investigation could be responsible for this paradox. It is interesting that there was no correlation between the magnitude of the enzymatic defect and the severity of clinical manifestations in any patient.

The occurrence of non-neuropathic Gaucher disease in infancy was noted 40 years ago (Aballi and Kato, 1938), but this form of the condition has been ignored in conventional classifications. However, in a report of these infants with hepatosplenomegaly, Schneider *et al.* (1977) drew attention to early onset and rapid progression in certain non-neuropathic cases.

The magnitude of the problem of early presentation is highlighted by the fact that we found only one patient with the classical infantile neuropathic type of Gaucher disease, in contrast with the 13 children who had the atypical non-neuropathic form. This 13-fold preponderance is of considerable importance from the point of view of differential diagnosis in any child with unexplained hepatosplenomegaly.

We thank our colleagues at the Red Cross War Memorial Hospital and other centres for access to their patients, R. A. De Méneaud for the illustration, and Mrs Greta Beighton and Mrs Barbara Breytenbach for typing the manuscript.

This investigation was supported by grants from the Mauerberger Foundation, the University of Cape Town Staff Research Fund, and the South African Medical Research Council.

Chorioamnionitis and funisitis due to *Corynebacterium kutscheri*

W. F. FITTER, D. J. DE SA, AND H. RICHARDSON

Department of Pathology, McMaster University Medical Centre, Hamilton, Ontario, Canada

SUMMARY When isolated from the female genital tract, diphtheroids are usually regarded as commensal organisms. *Corynebacterium kutscheri* however is a pathogen in laboratory rodents. We report a case in which *C. kutscheri* was isolated as a pure culture from the umbilical cord and from other surface sites in an infant. Histological examination of the cord and membranes demonstrated the organisms within these fetal tissues. The organisms evoked a fetal cellular response. The importance of recognising commensals as potential pathogens in states of altered host resistance is stressed.

Chorioamnionitis (inflammation of fetal membranes and the fetal surface of the placenta) and funisitis (inflammation of the umbilical cord) are often caused by ascending infections from the lower genital tract, and organisms that are regarded as normal commensals in this area are generally responsible. Although diphtheroids are part of the normal flora of the genital tract (Leppäluoto, 1974; Galask *et al.*, 1976) and have been isolated from the placental fetal surface and the fetal membranes (Benirschke and Driscoll, 1967), their pathogenicity is uncertain. As Benirschke and Driscoll (1967) stated, 'Results of cultures *per se*, were inconclusive. Doubtless this was because most of the placentas had traversed the lower genital tract prior to examination, and because the cultures were then taken from the exposed amniotic surface. However, taken in conjunction with other data, bacteriological cultures become very useful'.

It is worth re-emphasising that an 'infection' is usually defined as the invasion and multiplication of an organism within living tissues of the host (Walter and Israel, 1974). This report describes what we believe may be the first case of infection of the fetal membranes and cord in an infant due to a *Corynebacterium* species.

Case report

A baby girl was born prematurely at 26 weeks' gestation to a 42-year-old grand multiparous woman. Labour had started 24 hours earlier and was associated with leakage of amniotic fluid. Further rupture of membranes with discharge of amniotic fluid occurred immediately before birth. The baby was delivered vaginally as a vertex presentation. Apart from the sustained onset of premature labour, the pregnancy had been uneventful.

The infant weighed 980 g with an Apgar score of 3 after one minute and required assisted ventilation. The infant had periodic apnoea during the first 24 hours after delivery and was hypothermic.

Laboratory investigations were undertaken to exclude the possibility of sepsis and the infant was noted to have a WBC of $17 \cdot 4 \times 10^9/l$ with a pronounced 'shift-to-the-left', and 20% of the white cells were 'band cells'. The cord haemoglobin was 16·6 g/dl. No growth was obtained from a blood culture or cerebrospinal fluid specimens. Cultures from the umbilical cord, fetal membranes, rectum, nose, throat, eye, and external ear gave a pure growth of an aerobic Gram-positive bacillus.

Bacteriological studies. The rods were slender and clubbed and some had pointed ends. Staining was irregular and metachromatic granules were present. When cultured on blood agar plates the organisms were greyish in colour with an irregular edge, and measured about 2 mm after overnight incubation. There was no evidence of haemolysis. The organisms fermented sucrose, and produced urease. Nitrate was not reduced and gelatinase was not produced. The organism was identified as *C. kutscheri*, and this was confirmed by the external reference centres at the Hospital for Sick children, Toronto, and the Central Public Health Laboratory, Toronto.

Chest *x*-rays showed bilateral infiltrates which

Department of Pathology, McMaster University Medical Centre, Hamilton, Ontario
W. F. FITTER, chief resident
D. J. DE SA, staff pathologist
H. RICHARDSON, staff microbiologist

increased during the next 24 hours, and these changes were considered to be consistent with a pneumonitis. After treatment with ampicillin and gentamicin there was considerable improvement in the infant's body temperature and a slow resolution of the pulmonary infiltrates was seen on subsequent x-rays. The abnormalities in the blood film disappeared gradually over a week. No organism was recovered at any time from the tracheal aspirates, however, and there was no firm microbiological confirmation of a *C. kutscheri* pneumonitis.

Pathological studies. The placenta, membranes, and cord were available for pathological examination. The placenta weighed 300 g with obvious discoloration of the fetal membranes by multiple, minute, greyish-brown plaques on the amnion. Similar minute plaques, 0·2–0·5 mm in diameter, were identified on the surface of the umbilical cord (Fig. 1). Microscopical examination showed a florid chorioamnionitis and funisitis (Fig. 2). The plaques consisted of minute central necrotic foci with aggregates of mononuclear cells forming a boundary around invading colonies of Gram-positive bacilli (Fig. 3). In some of the organisms metachromatic granules were present. The organisms penetrated into and proliferated within the subamniotic mesenchyme of the fetal surface of the placenta, and Wharton's jelly in the umbilical cord. Fetal inflammatory cells could be seen migrating through the walls of the umbilical vessels in the cord and on the fetal surface of the placenta towards the invading organisms. There was no evidence of inflammation of chorionic villi. The histological appearances were of a chorioamnionitis and funisitis, in which it was possible to demonstrate invading and proliferating organisms, morphologically compatible with those isolated from the surface of the cord and membranes, evoking a fetal inflammatory cellular reaction.

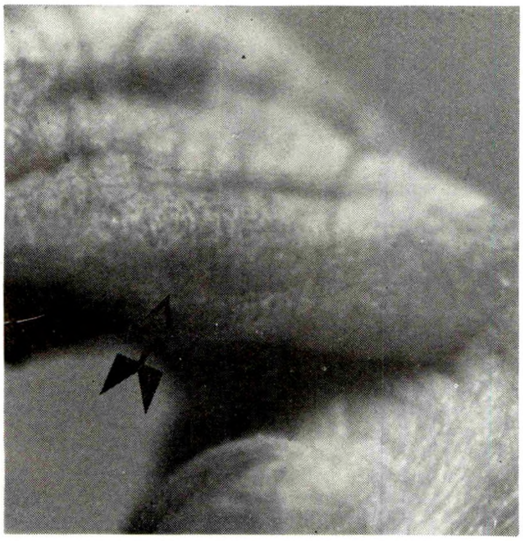

Fig. 1 *Close up view of surface of umbilical cord of infant showing the multiple small greyish-brown plaques (arrow) on its surface (approximately × 2 magnification).*

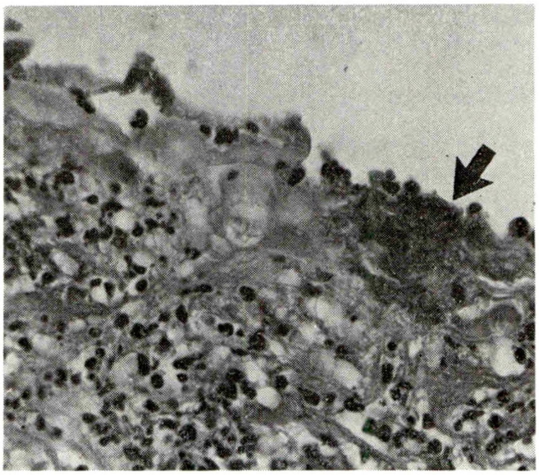

Fig. 2 *Microscopical section through umbilical cord showing the proliferating colony of diphtheroids (arrow) and the cellular inflammatory response in Wharton's jelly. Papanicolaou's stain,* × 800.

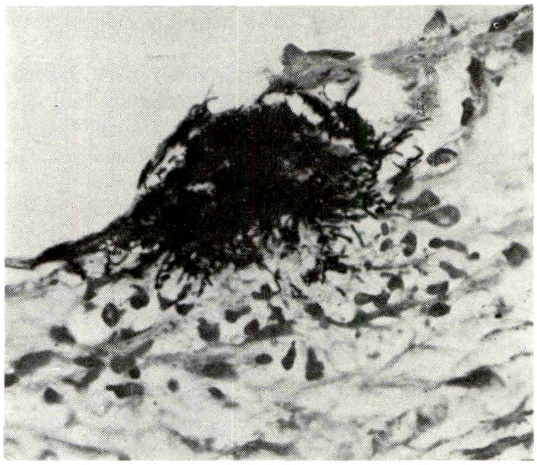

Fig. 3 *Gram stain of one of the plaques seen in Fig. 1, showing the proliferating Gram-positive rods within Wharton's jelly. Note also the early cellular response to the organism. Gram stain,* × 800.

Follow-up. This baby has been followed up repeatedly after being discharged at 11 weeks (postnatal age). Weight gain has been slow, but consistent, and the infant appears otherwise normal in all respects at age 2 years.

Discussion

Ascending infections of the female genital tract are associated most commonly with isolates of *Escherichia coli*, anaerobic cocci, and *Bacteroides* species (Galask *et al.*, 1976), all flora that normally inhabit the female genital tract (Tashjian *et al.*, 1976).

C. kutscheri (formerly classified as *Corynebacterium murium*) has been known to be a cause of pseudotuberculous, granulomatous infection in laboratory rodents (Fauve *et al.*, 1964; Pierce-Chase *et al.*, 1964). However, like other diphtheroids, it is regarded as a normal commensal when isolated from the female genital tract (Galask *et al.*, 1976; Tashjian *et al.*, 1976). Diphtheroids are, of course, recognised often on routine cervical cytological examination in asymptomatic women (Leppäluoto, 1974). In fact, diphtheroids are such common inhabitants of the vagina that they can prove a source of diagnostic confusion as pathogenic *Listeria monocytogenes* may be wrongly classed as diphtheroids (Morison, 1970).

As the fetal skin surface, umbilical cord, placenta, and membranes may be expected to be contaminated with vaginal organisms during their passage through the genital tract (Benirschke and Driscoll, 1967), the isolation of a commensal organism does not on its own constitute proof of its pathogenicity or its aetiological role in producing chorioamnionitis.

As has been shown by many workers (summarised by Benirschke and Driscoll, 1967) diphtheroid organisms are often isolated from a variety of cultures of the vaginal cavity (Weinstein, 1938; Torrey and Reese, 1945), amniotic surface (Driscoll, 1967), and even from cultures of blood sampled through the umbilical cord (Kobak, 1930). In all these reports diphtheroids have never been reported in a *pure* culture, and in no instance was it suggested they were pathogenic.

In our patient however, we have been fortunate in demonstrating the invasion of fetal tissues by an organism that is often regarded as a banal commensal, and have been able to show it inducing an inflammatory response from the fetus. We were successful, furthermore in isolating it as a pure uncontaminated culture. It is possible for us to be confident, therefore, in identifying *C. kutscheri* as the causal agent in our particular infant's chorioamnionitis and funisitis. While we believe that this may be the first case where this organism has been implicated in an infection in humans, it is worth mentioning that the circumstances were fortuitous. It is probable, therefore, that other cases of *C. kutscheri* chorioamnionitis have occurred, but not been recognised or reported.

We believe that in our patient there were sufficient clinical grounds for suspecting a pneumonitis even though we were unable to obtain firm microbiological proof. The improvement in clinical status, in parallel with the changes in the *x*-rays of the chest and amelioration of the haematological abnormalities, after appropriate treatment with antibiotics does not mitigate against this view.

This case indicates the importance of recognising the possible role of commensals as potential pathogens when host resistance may be altered, as in extreme immaturity and in the presence of leaking amniotic fluid, with a breakdown in the natural barriers to infection. In such a situation the isolation of pure cultures, even of commensal micro-organisms, demands careful assessment and close co-operation between microbiologist and pathologist.

Short reports

Rectal aspirin—absorption and antipyretic effect

KEVIN CONNOLLY, L. LAM, AND O. C. WARD

Children's Research Centre, Our Lady's Hospital for Sick Children, Dublin

SUMMARY Rectal acetylsalicylic acid was given to 14 children who had undergone open heart surgery. The effect on their temperatures was similar whether 15–30 or 30–50 mg/kg was given. Either dose was more effective than no treatment. The greatest fall in temperature occurred after 4 or 5 hours. Rectal aspirin in a triglyceride base is effective in lowering postoperative temperature. It should also be of use in treating other fevers. A dose of 20–25 mg/kg is suggested.

There are several reasons for raised temperatures in postoperative patients apart from infection. Fluid restriction after some types of surgery, and endogenous pyrogen release by leucocytes are two reasons for such pyrexia. However, there is no evidence that this pyrexia plays any beneficial role in aiding the inflammatory response. On the contrary, the increased metabolic rate resulting from raised body temperature may increase the stress to the patient. It is reasonable therefore to attempt to reduce such pyrexia, particularly after major surgery.

Aspirin is an effective antipyretic, and is better and more comfortable than tepid sponging (Hunter, 1973). There are conflicting reports concerning the usefulness of rectal aspirin (Samelius and Åström, 1958; Nowak *et al.*, 1974), and anyway they concentrated on the urinary recovery of salicylate in healthy subjects, rather than on the clinical effectiveness of rectal aspirin.

This trial was carried out with the following aims: (1) to assess the effect of rectal aspirin in lowering temperature after cardiac surgery; (2) to determine the duration of action of a single rectal dose; (3) to determine a weight-related dose for rectal aspirin; (4) to assess the safety of rectal aspirin.

Patients and method

19 children aged between 3 and 14 years who had undergone open heart surgery were studied. All had arterial and venous cannulae and a pulmonary artery temperature probe in place. Acetylsalicylic acid in a triglyceride base was given as a single dose into the rectum. Suppositories contained either 150 or 300 mg aspirin. Seven of the 19 children were given between 15 and 30 mg/kg, the mean dose being 23 mg/kg. Seven children were given between 30 and 50 mg/kg, with a mean dose of 44 mg/kg. The remaining 5 children were used as controlsy 1 ml blood was obtained before and then hourln for 7 hours after the suppositories had been inserted. Pulmonary artery and peripheral temperature were recorded throughout the trial.

No patient developed a clinically obvious infection for 72 hours after the trial. Serum salicylate was measured using the method of Keller (1947), modified for use in an ABA-100 analyser.

Results

The serum salicylate levels, attained after different doses are shown in Fig. 1. The greatest levels were reached 3 or 4 hours after administration. There was very little fall-off in serum levels up to 7 hours after administration. Levels achieved at any time after the higher dose were almost twice those attained after the lower dose, although the two

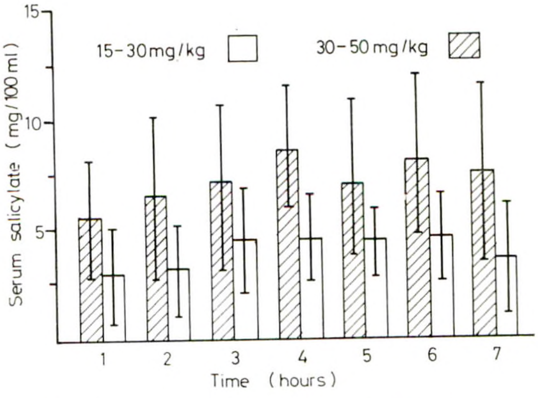

Fig. 1 *Serum salicylate levels (mean ± SD) after rectal acetylsalicylic acid.*

groups overlapped. The highest serum level reached in any patient was 14 mg/100 ml (1·0 mmol/l), 6 hours after insertion of the suppositories. Low serum levels were achieved initially in 2 patients whose core-peripheral temperature gradients were more than 8°C for the first 3 hours of the trial.

The temperature pattern in the three groups is shown in Fig. 2. The mean temperature at the time of administration was somewhat lower in those who received the smaller dose, but throughout the period of observation the temperatures between the three groupings overlapped. The temperatures in those who received no aspirin tended to remain constant. Both groups who received rectal aspirin showed a fall in mean temperature of 0·9–1·0°C. The lowest mean level was reached after 4 hours in the low-dose group and after 5 hours in the high-dose group.

All subjects retained the suppositories throughout the trial, and in no patient did rectal bleeding occur.

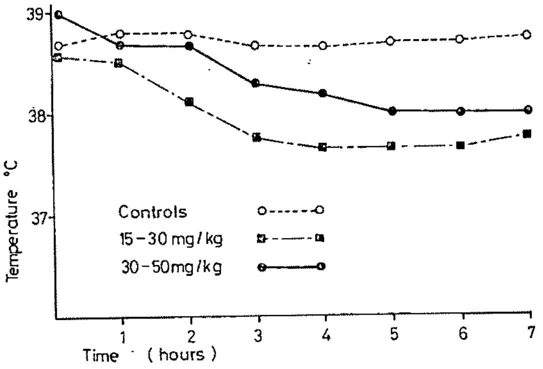

Fig. 2 *Temperature pattern after rectal aspirin.*

Discussion

The peak serum level after oral salicylate is reached after 2 hours (Lowenthal *et al.*, 1970). The peak level after rectal administration occurs later. When a rapid antipyretic effect is sought, the oral route should be used. However, when temperature reduction is not urgent, or in cases where the patient is vomiting or is unable to swallow, the rectal route is a useful alternative. The delay in attaining a peak serum level after rectal administration reduced the incidence of side effects (Borg *et al.*, 1975).

Results reported by Parrott (1971) suggest that the mucosa of the entire gastrointestinal tract has the same absorption characteristics for aspirin. The suppository base used is one factor that may influence absorption from the rectum (Samelius and Åström, 1958; Gibaldi and Grundhofer, 1975). The triglyceride base used in this trial has a melting point of between 33·5 and 35·5°C and a hydroxyl value below 2, and thus it is appropriate to use it for rectal acetylsalicylic administration as long as the rectal temperature is above 33·5°C.

The retention time influences the amount of aspirin absorbed (Nowak *et al.*, 1974). In all subjects in the present study the suppositories were retained throughout the 7 hours, thus a large percentage is likely to have been absorbed.

The overall rate of absorption in the 14 patients was good, although there was individual variation. This was particularly pronounced in the 2 patients with large core-peripheral temperature gradients. It is probable that these 2 had rectal vasoconstriction while the large gradient persisted, resulting in very slow absorption.

The doses used in this trial were higher than those recommended for oral administration. However, the maximum serum level reached in any patient was well below the toxic level. The LD 50 of rectal acetylsalicylic acid in rats is 790 ± 27 mg/kg (Coldwell and Boyd, 1966); the doses used in the present trial were well below this amount.

The optimum serum salicylate level for temperature reduction is not known. The level possibly depends on the aetiology of the pyrexia, and the sex and age of the patient. There is probably individual variation in the response to a given salicylate level.

Our results suggest that 3–5 mg/100 ml is as effective as a level of 5–10 mg/100 ml in postoperative pyrexia. This may be the result of an equal effect on prostglandin levels in the hypothalamus by any serum salicylate level below about 15 mg/100 ml. It is of interest that this level is lower than that needed for an anti-inflammatory or an analgesic effect. Also, the wide range of apparently effective levels is of interest in view of the large variations in plasma levels attained after a given oral dose of salicylate (Bardare *et al.*, 1978). It thus may be reasonable to recommend a dose on a 'per kilogram' basis in spite of the variation in plasma levels after oral rectal salicylate.

We thank Mr D. Kenny and staff in the Biochemistry Department of Our Lady's Hospital for Sick Children for performing the serum salicylate levels, and the nurses in St Patrick's Ward for their help in recording the observations. We also thank Rice Steele & Co. for supplying the suppositories.

Thrombocytosis in low birthweight infants

A physiological phenomenon in infancy

ULLA LUNDSTRÖM

Children's Hospital, University of Helsinki, Finland

SUMMARY Prematurity has traditionally been connected with thrombocytopenia, although this is unlikely to be associated with prematurity itself but rather with serious illnesses in such infants. Platelet counts were measured in 117 healthy preterm infants with birthweights <2000 g, who were followed up from 2 weeks to 6 months. In this series the platelet counts were high compared with those in previous reports, and also compared with what is considered normal for term infants. The 95% range was between 160 and 675 × 10^9/1, with a median value of 375 × 10^9/1. The data suggest that thrombocytosis is a phenomenon related to prematurity.

There have been conflicting reports on platelet counts in preterm infants during the first weeks of life and little information about platelet counts after 2 months. Medoff (1964) found low values in infants with birthweights <1700 g, as did Kaplan and Klein (1962). Aballi *et al.* (1968) reported considerably higher values with a mean value >200 × 10^9/1 at 1–2 days and >300 × 10^9/1 at 2 weeks and at one month in a large series of 300 premature infants. They excluded 10% of the infants because they were ill or subsequently died, and concluded that the abnormally low values in earlier reports might be associated with serious illnesses which result in thrombocytopenia. Evidence of illness was also found in many premature infants who had low platelet values (Oztalay and Beard, 1963). Abnormally high values have been reported in connection with haemolytic anaemia due to vitamin E deficiency (Ritchie *et al.*, 1968). Melhorn and Gross (1971) found platelet counts of between 400 and 450 × 10^9/1 in 10 infants with anaemia, reticulocytosis, and low levels of serum vitamin E concentration who were aged 6–8 weeks. The platelet count subsequently decreased when the infants were treated with oral vitamin E.

The purpose of this study was to establish the platelet counts in preterm infants who were followed longitudinally and for a sufficiently long time to exclude any sick infant; iron and vitamin E deficiency was prevented by giving daily supplements.

Subjects and methods

At age 2 weeks a group of 125 healthy preterm infants with birthweights between 1050 and 2000 g was studied (Lundström *et al.*, 1977). None then had had exchange transfusion, but 7 had transfusions later and so were excluded. One infant with hereditary spherocytosis was also excluded. Thus the study group comprised 117 infants who were tested at 2 weeks and then each month until aged 6 months, on average five times per infant. Gestational age according to amenorrhoea ranged from 27 to 40 weeks (mean 32 weeks); the average birthweight was 1650 g.

During the follow-up period the infants received either breast milk, proprietary infant milk formula, or home-prepared cows' milk dilution. In addition to vitamins A, D, and C, and folic acid, each infant was given a daily dose of 5 IU vitamin E as alpha-tocopherol acetate beginning at age 2 weeks. Thus the ratio of vitamin E to polyunsaturated fatty acids in the three milk diets ranged from 1·6 to 5·0, and exceeded the amount normally considered sufficient to prevent vitamin E deficiency (Horwitt *et al.*, 1963). The infants with uneven birth dates received 2 mg/kg elemental iron each day starting at 2 weeks, while babies born on even dates were not given additional iron before 6 months unless there were signs of iron depletion in their haemoglobin (Lundström *et al.*, 1977).

Hb concentration and reticulocyte and platelet counts were determined from capillary samples during the initial period in hospital and from venous blood at subsequent outpatient visits. Hb was measured by a Model S Coulter Counter. Reticulocytes were determined microscopically. Platelet counts were performed by a direct chamber count method (Wright and Kinnicutt, 1911).

Results

There was evidence of thrombocytosis in preterm infants aged between 2 weeks and 6 months. However, there was a wide range of values at each age and a great variation within single infants at different times (Figure). The 95% range of all the babies with their ages combined was between 160 and 675 × 10^9/l, with a median of 375 × 10^9/l. Only a few infants had transient low values <200 × 10^9/l.

There was no difference in platelet counts between infants who were given iron and those who were not (Figure). At each age the groups of infants with platelet counts above or below 400 × 10^9/l had similar values for Hb and reticulocyte counts, except at 2 weeks of age when the group with the high count had a lower concentration of Hb ($P<0\cdot05$). In order to test the correlation between gestational age and platelet count the two extreme groups, those with gestational age <31 weeks and those with gestational age >34 weeks were compared. No difference was found, nor was there any correlation between birthweight and platelet count.

Discussion

In this series of premature infants the platelet counts were high compared with other reports (Kaplan and Klein, 1962; Medoff, 1964), and also compared with what is considered normal for term infants. In

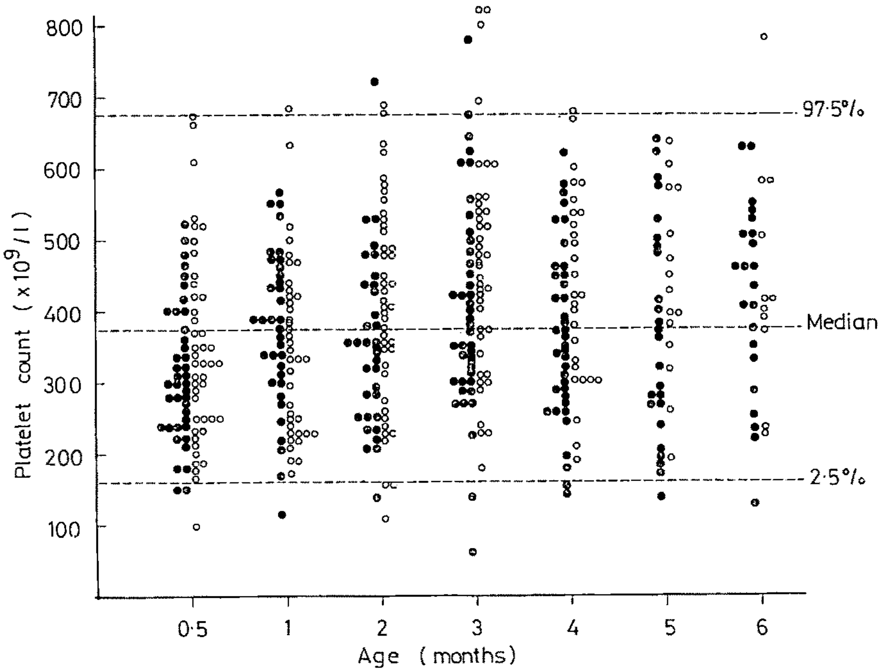

Figure *Platelet counts in low birthweight infants.* ● = *iron-supplemented,* ○ = *nonsupplemented infants. Median and 95% range of all values is shown.*

infancy and childhood, thrombocytosis is seen in connection with various rare diseases (Addiego *et al.*, 1974) of which iron deficiency and vitamin E deficiency are likely to be the most common causes in preterm babies. These results show that there were relatively high values at 2 weeks in the presence of ample iron stores. No difference was found between iron-supplemented and nonsupplemented infants. Nor were high platelet values associated with low Hb levels, except at 2 weeks. Accordingly there is no reason to suspect that a lack of iron in these infants individually, or as a group, would have resulted in thrombocytosis. Vitamin E deficiency as a cause is also unlikely as the infants were supplemented with vitamin E, and Hb levels and reticulocyte counts were similar whether their platelet counts were high or low.

The data suggest that thrombocytosis is a physiological phenomenon in preterm infants during the first 6 months of life. The increase in number might be compensatory to a decreased functional capacity shown in term infants (Corby and Schulman, 1971) and further suggests that values $<160 \times 10^9/1$ are evidence of thrombocytopenia.

This study was supported by grants from the Foundation for Paediatric Research in Finland, and by National Institutes of Health Grant No. AM HD 13897 and National Foundation, March of Dimes Grant No. 6–81.

Aortography in infantile coarctation

A simple and effective technique

BRIAN DENHAM, O. C. WARD, PATRICK McCANN, AND NOEL BLAKE

Cardiac Department, Our Lady's Hospital for Sick Children, Dublin

SUMMARY A new and simple technique is described which clearly defines the aortic anatomy in infantile coarctation. The technique greatly helps to select those neonates whose lives can be salvaged by early surgery. There have been no serious adverse effects.

Coarctation in the neonate when associated with an interventricular septal defect or patent ductus arteriosus is a disorder which carries an extremely high mortality, in the region of 80 to 90% in the first year of life. It is usually associated with hypoplasia of the distal aortic arch and may be regarded as the mildest expression of the hypoplastic left heart syndrome.

In some cases surgery in the first months of life to relieve the coarctation and close a patent ductus arteriosus can reduce the left ventricular pressure and thus the left-to-right shunt through the residual interventricular septal defect to a tolerable level. The infant's outlook then becomes that of an uncomplicated ventricular septal defect which may even proceed to spontaneous closure. The crucial factor in improving the survival rate for infants with infantile coarctation is the selection of those infants who will benefit from early surgery. This requires adequate definition of the vascular anatomy in the area of the coarctation and has until now required arteriotomy with its inherent risk to subsequent growth of that limb, thrombosis, and many other complications. The large left-to-right shunt through an intraventricular septal defect means that left ventriculography usually provides inadequate definition of this area (Gyepes and Vincent, 1974).

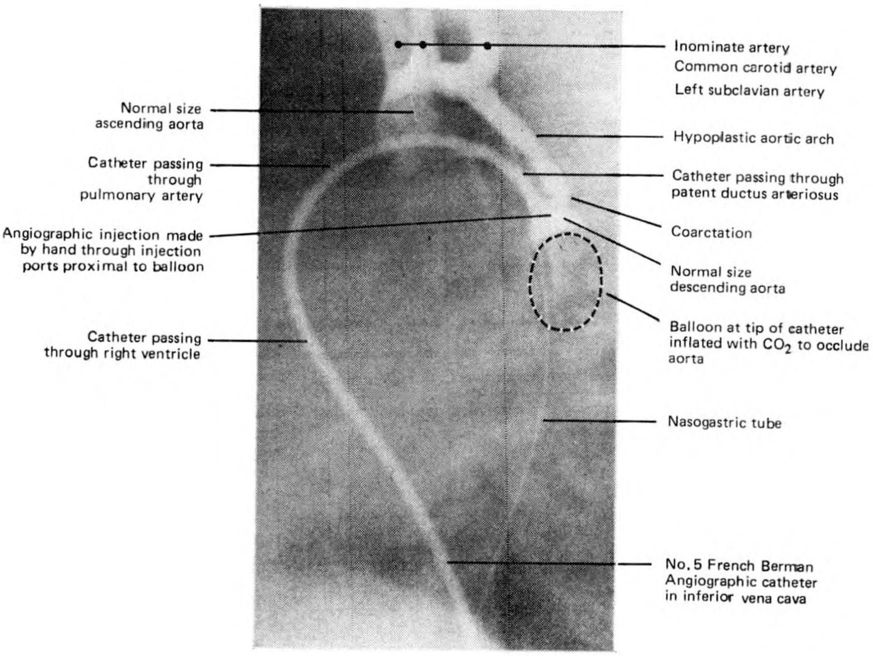
Method

The use of a balloon angiocatheter floated antegradely from the pulmonary artery through the patent ductus arteriosus into the aorta permits the affected segment to be easily demonstrated (Figure). After inflating the balloon with carbon dioxide or dilute contrast medium so as to occlude the descending aorta completely, contrast is immediately injected into the aorta through the injection port proximal to the balloon and retrograde filling of the aortic arch allows cineangiograms of high quality to be obtained (Denham, 1978).

Discussion

So far this technique has been used in 12 infants and excellent angiograms have been obtained in each. There have been no adverse effects apart from transient hypertension such as often occurs after any angiogram. The precaution should be taken of using a nontoxic medium for inflation in case the balloon ruptures, and aortic occlusion should be carried out in the shortest possible time. The duration of aortic occlusion may be kept shorter than 10 seconds if carbon dioxide is used to inflate the balloon and if the angiographic injection is made by hand. Connection of the catheter to a mechanical injector and the use of dilute contrast medium for inflation both prolong the time of aortic occlusion, and for these reasons carbon dioxide inflation and manual injection are preferred.

The catheters so far used for this procedure are: No. 5 French and No. 6 French Berman Angiographic balloon catheters manufactured by American Catheter Corporation N.J. The diameter of the balloon at maximum inflation is 10 and 12 mm and



Normal size ascending aorta
Catheter passing through pulmonary artery
Angiographic injection made by hand through injection ports proximal to balloon
Catheter passing through right ventricle
Inominate artery
Common carotid artery
Left subclavian artery
Hypoplastic aortic arch
Catheter passing through patent ductus arteriosus
Coarctation
Normal size descending aorta
Balloon at tip of catheter inflated with CO_2 to occlude aorta
Nasogastric tube
No. 5 French Berman Angiographic catheter in inferior vena cava

Figure *Left lateral projection of 2·5 kg one-month-old infant.*

these catheters can therefore easily occlude the neonatal descending aorta, the internal diameter of which is 5 to 6 mm (Scammon, 1959).

This technique could be applied in other anatomic cases in which angiograms are difficult to obtain; it is particularly suitable for the neonate.

Frequency and weight of normal stools in infancy

J. N. LEMOH AND O. G. BROOKE

Department of Child Health, St George's Hospital, London

SUMMARY These data give a guide to the range of stool weights and their frequency at different ages in infancy. The constancy of stool water content is emphasised.

Burkitt (1976) complained that there are no data on stool weights in normal infants. We have therefore undertaken to provide data on the variation in frequency, weight, and water content of the stools for a group of normal babies and young children fed on cows' milk formulae and mixed diets. The much looser stools of breast-fed infants prevented their inclusion in the study, because it was not possible to prevent spillage.

Materials and methods

Infants. 55 healthy infants aged between 3 days and 2 years were studied, after obtaining parental cooperation. 33 of the infants were in hospital during the study; 16 of these were aged 3–6 days (normal neonates) and the remaining 17 were in hospital for social reasons. At least 3 days were allowed for these infants to become accustomed to the hospital before collections began. The remaining 22 babies were studied in their homes. The neonates and infants under 4 months were fed *ad libitum* on proprietary milk formulae, and older infants were on a mixed diet of cereals and formula milk or unmodified cows' milk. Infants who were unwell or who had gastrointestinal symptoms were excluded.

Stool collections. Stools were collected in rayon napkin liners for 3–9 days, median 3·5. A series of *in vitro* experiments was carried out to determine whether stools collected in this way absorbed water from wet napkins or released water into dry napkins:

Effect of wet napkins
12 random stool samples weighing, with their liners, between 8·6 and 46·1 g were incubated for 2 hours in disposable napkins which had been soaked in normal saline, whose osmolality approximates that of urine. The stools and liners were then reweighed. Mean weight of stools and liners before incubation was 21·2 g, SD 11·0, and after incubation 21·0 g, SD 10·0. Mean change in stool and liner weight was −0·6%, which was not significant.

Effect of dry napkins
12 further random stool samples in liners were incubated for 2 hours in dry disposable napkins. Mean weight of stools and liners before incubation was 18·5 g, SD 8·2, and after incubation 18·1 g, SD 8·1. Mean change in stool and liner weight was −2·7%, again not significant. These findings were confirmed by detecting no significant increase in postdefecation napkin weight when stools were collected in napkin liners in infants wearing urine collection bags.

All stool collections were therefore made by this method, which proved reliable provided that the liners were properly fitted, and enabled stools to be collected at home over reasonable periods of time. At each napkin change, stool adhering to the buttocks was wiped off with the edge of the liner, and the stool and liner were then sealed in plastic bags, labelled with date and time, and frozen. Wet stool weights were subsequently measured in the laboratory, and the stools were freeze dried to determine water content.

Results

The results are shown in the Table, which divides the children arbitrarily into four age ranges. A total of

Table *Data on stool frequency, weight, and water content in normal infants at different ages*

	1st week	*8–28 days*	*1–12 months*	*13–24 months*
No. of infants	16	11	11	17
No. of stools	278	139	88	136
Stool frequency				
Mean interval between stools (hours) ±1 SD	5·2±1·9	9·9±6·5	13·2±9·2	14·9±8·3
Range (hours)	0·5–22	0·7–38·5	0·5–53	2–120
No. of stools per 24 h ± 1 SD	4±1·8	2·2±1·6	1·8±1·2	1·7±0·6
Range	1–12	0–6	0–5	0–3
Weight of individual stools (g)				
Mean	4·3	11·0	17	35
Range	0·5–48	0·3–40	2–98	4–180
Stool water content (%)				
Mean ± 1 SD	72·8±5·0	73·3±2·7	75·0±3·0	73·8±3·2
Range	65–84	72–77	72–80	66–81

641 stools were examined. As expected there was a wide range of individual variation in stool weight and frequency, but the general trend of an increase in weight and decrease in frequency with age is apparent. However, even in the second year it was common for the children to pass more than one stool a day, although some children went for 2–3 days without defecation in the absence of clinical 'constipation'. Stool water content hardly varied from the first week to the second year and had a remarkably small SD. There was no correlation between stool frequency and stool weight.

Comment

The only published information on defecation patterns in infancy is by Colón and Jacob (1977) who investigated the subject by using questionnaires. The parents in their study reported that more than half the children passed one stool daily after 18 months. These findings seem on the optimistic side for British children who on average continue to pass more than one stool per 24 hours until 2 years of age. Colón and Jacob (1977) obtained no data on stool weights.

The surprising finding in this investigation was the constancy of stool water content, apparently finely controlled to maintain an even stool consistency throughout the age range. Since stool water is easy to measure and remains so constant in health, it could be an unnecessarily neglected marker of gastrointestinal disease and deserves future study.

We intend that the range of variation in stool weight and frequency given in the Table should give some long-needed guidance for child health workers as to what constitutes 'normality'. The study also confirms the effectiveness of napkin liners.

We acknowledge the invaluable help of Mrs M. Lewis in the data collection.

Infantile hypertrophic pyloric stenosis—unusual familial incidence

V. R. FINSEN

Department of Surgery, Paediatric Section, Regionsykehuset, Trondheim, Norway

SUMMARY A man, who had been treated for infantile hypertrophic pyloric stenosis (PS), was found to have 3 sons with the same condition. A genealogical table of his family showed that both his parents had relatives with PS. So far as it was known, none of his wife's relatives had the condition. It is suggested that the man's parents carried genes predisposing to PS and transmitted these to him in such quantity that he and all his children acquired the condition.

The aetiology of infantile hypertrophic pyloric stenosis (PS) is largely unknown. It has long been recognised that there is an increased preponderance of the condition in the relatives of patients. This familial predisposition is shown very clearly in the family to be described.

A patient (IV_4 in the Figure) had an operation at this hospital some years ago for PS. On further investigation it was found that both his brothers (IV_3 and IV_5) and his father (III_6) had been treated for the same condition. The main features of their case histories are summarised in the Table.

A genealogical table stretching over four generations was assembled for this family (Figure). The patient's mother had no known relatives with PS, but both his paternal grandfather and grandmother (II_3

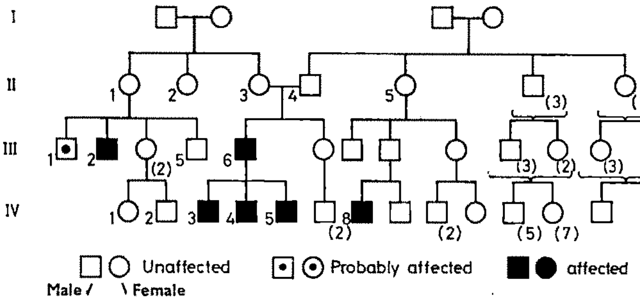

Figure *Genealogical table of family with infantile hypertrophic pyloric stenosis. Roman numerals indicate generation. Arabic numbers indicate number in generation. Figures in brackets indicate the number of unaffected individuals.*

Table *Main features of the case histories of Case III$_6$ and his 3 sons IV$_3$, IV$_4$, and IV$_5$*

Case	*Gestation at birth (weeks)*	*Start of projectile vomiting*	*Clinical findings*	*Treatment*	*Outcome*
III$_6$	40	3rd week	Case notes lost	Spasmolytics and frequent small feeds	Projectile vomiting ceased after few weeks. Uneventful recovery
IV$_3$	40	2nd day	Tumour palpated. Hypertrophy on *x*-ray	Pyloromyotomy at 4 days	Reoperated next day because of gastric retention. Diaphragm in pyloric region excised. Uneventful recovery
IV$_4$	38	3rd week	Tumour palpated. Visible peristalsis. *X*-ray normal	Pyloromyotomy at 3 weeks	Uneventful recovery
IV$_5$	40	3rd day	First *x*-ray normal. Hypertrophy on *x*-ray after 10 days	Pyloromyotomy at 2 weeks	Uneventful recovery

and II$_4$) had. Cases III$_2$ and IV$_8$ had both had pyloromyotomies performed, and III$_1$ had died on his way to hospital when he was 7 weeks, after suffering projectile vomiting and progressive weight loss from age 2 weeks.

There was no history of marriage between relatives.

Discussion

Although PS is found in infants it is not congenital in the sense that it is present at birth. The symptoms usually present between ages 3 and 6 weeks, and only rarely during the first week. All reported series show a pronounced preponderance of male to female patients, and it has long been noted that there is an increased incidence of PS in the relatives of patients who have the condition. Carter and Evans (1969) studied 813 patients treated by Ramstedt's pyloromytomy between 1920 and 1949; 20% of the sons and 7% of the daughters of their female patients had developed PS, but only 5% of the sons and 2·5% of the daughters of the male patients had developed the condition. They estimated the incidence in the general population as being 0·5% for liveborn boys and 0·1% for liveborn girls. They concluded that the hereditary background to PS is polygenic.

It would appear that there are a number of genes in different locations which may predispose for PS, and that it is necessary for a certain number of these genes to code for the condition for it to develop. The female phenotype seems to be protected to some degree so that a greater genetic load is required for girls to acquire the disease. This greater genetic load explains why the children of female patients are more likely to develop PS rather than those of male patients.

It is interesting to note that Cases IV$_3$ and IV$_5$, who were born at term, developed the symptoms at an exceptionally early age. There was little time for any postnatal environmental factors to influence the development of the condition in them. Their brother, Case IV$_4$, was born 2 weeks preterm and PS was diagnosed at age 3 weeks. All 3 brothers, therefore, developed the condition at about the same time after conception.

It is not certain from whom Cases III$_1$, III$_2$, and IV$_8$ acquired their predisposition for PS. However, finding the condition in these patients increases the likelihood of Cases II$_3$ and II$_4$ carrying genes predisposing to PS, although not to such a degree that they developed the condition. These genes were inherited by their son (Case III$_6$) in such quantity, that not only did he develop PS, but he transferred the condition to all his 3 children.

Discontinuation of continuous positive airways pressure in infants with respiratory distress syndrome

THOMAS HEGYI AND I. MARK HIATT

Division of Perinatology, Monmouth Medical Center, and the Department of Pediatrics, Hahnemann Medical College and Hospital of Philadelphia

SUMMARY Unexpected stability of arterial oxygen and carbon dioxide tensions occurred in infants recovering from respiratory distress syndrome (RDS) on the abrupt withdrawal of CPAP at 6 cmH_2O pressure. 30 preterm infants (birthweights 880–3200 g gestational ages 29–38 weeks) were treated at a mean age of 10 hours and for a mean duration of 62 hours. CPAP was stopped when F_IO_2 requirement fell below 0·3, and stable Po_2 was maintained for 4 hours. Discontinuation of CPAP at 6 cmH_2O resulted in a mean change in Po_2 from 66 to 64 mmHg (8·8 to 8·5 kPa) and a mean change in Pco_2 from 41 to 40 mmHg (5·4 to 5·3 kPa). We conclude that this population of infants suffering from moderate RDS tolerated the abrupt withdrawal of CPAP, and that gradual reduction of pressure was unnecessary.

It is now over 7 years since CPAP was recognised as an effective mode of treatment for infants suffering from respiratory distress syndrome (RDS) (Gregory *et al.*, 1971). However there are still many unanswered questions before the maximum benefit-risk ratio is attained: the best time and mode for instituting treatment, the most efficient pressures, the techniques for monitoring complex physiological processes, and the optimal time and method for stopping treatment. With regard to this last, a prospective trial was designed to determine the effect on arterial blood–gas tensions of removing CPAP without the generally accepted weaning procedure (Llewellyn and Swyer, 1973; Krouskop *et al.*, 1975; John *et al.*, 1976; Stark and Taeusch, 1977).

Patients and methods

During the 7-month period from 1 July 1977 to 31 January 1978, 41 infants suffering from RDS were admitted to the neonatal intensive care unit. Of these infants, 30 required treatment with CPAP as the sole form of support, while 11 were treated with mechanical ventilation. The former group of infants comprised the study group.

CPAP was delivered by a nasal prong device (Wung *et al.*, 1975) at a pressure of 6 cmH_2O. This applied pressure measured at the nares was kept constant and F_IO_2 was altered throughout the course of treatment in order to maintain Po_2 in the 50–80 mmHg range. The criteria for stopping CPAP were: ambient oxygen requirement of 0·3 or less to maintain Po_2 above 50 mmHg, a stable Po_2 at this level of support for 4 hours, and the absence of clinical signs of respiratory distress. Arterial blood samples were drawn from the umbilical catheter about 20 or 30 minutes before and after the withdrawal of CPAP and measured on an IL oxygen analyser (Instrumentation Laboratories: Lexington, Mass.).

The mean birthweight of the infants was 1920 g (range 800 to 3200) and the mean gestational age 34 weeks (range 29 to 38). Nine infants weighed <1500 g, 9 were between 1500 and 2000 g, and 12 were >2000 g.

RDS was determined by *x*-ray and clinical evaluation to be of moderate severity. A-aDo_2 values were calculated at the time that treatment with CPAP was started for a precise assessment of the disease. The A-aDo_2 before treatment was 217 + 110 mmHg (mean ± SD). 70% of the A-aDo_2 values were between 100 and 300 mmHg, and 23% were between 300 and 600 mmHg.

Results

CPAP was begun at a mean age of 10 ± 10 hours (mean ± SD). The mean duration of CPAP was 62 hours, SD 36. 14 infants reached the criteria for withdrawal by 48 hours whereas the remainder required 48 to 160 hours to reach this goal.

The response of the arterial blood–gases to the removal of CPAP was evaluated at a F_IO_2 of 0·26 ± 0·04 at an A-aDo_2 of 71 ± 28 mmHg. The Po_2 on CPAP was 66 ± 9 mmHg and off CPAP it was 64 ± 10 mmHg ($P>0·5$). The Pco_2 was 41 ± 7 mmHg before CPAP withdrawal and 40 ± 8 mmHg after ($P>0·5$). The distribution of Po_2 and Pco_2 values before and after CPAP was comparable (Figure). None of the infants needed to return to CPAP after it had been stopped.

Examination of the individual responses showed that 10 Po_2 values increased and 20 decreased, while

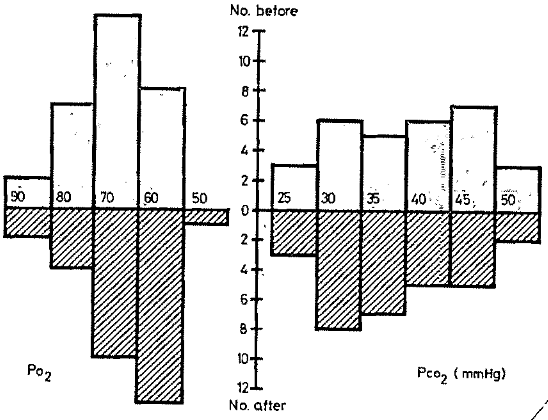

Figure *Distribution of Po_2 and Pco_2 before and after abrupt withdrawal of CPAP.*

9 Pco_2 levels increased and 18 decreased. In the data analysis a 10 mmHg change in Po_2 was assumed to be within normal limits of Po_2 variability, as suggested by observations during continuous monitoring with the transcutaneous oxygen electrode (Dangman *et al.*, 1976). Under these conditions 20 Po_2 values remained stable while 5 increased and 5 decreased. The Pco_2 before withdrawal was significantly lower in those infants in whom the Po_2 increased than in the other two groups ($P<0 \cdot 05$). A further comparison of these subgroups (Table) showed no significant differences with respect to birthweight, age at start, A-aDo_2 at start, duration of treatment, and the Pco_2 response to withdrawal.

The negative correlation between Po_2 before withdrawal and the Po_2 response remained significant in the analysis of all variables ($P<0 \cdot 05$). In addition, a significant positive correlation was noted between duration of treatment and Pco_2 before CPAP withdrawal ($P<0 \cdot 05$). No correlation was found between the Po_2 and Pco_2 responses and birthweight, gestational age, age and A-aDo_2 at the start, and F_IO_2 and A-aDo_2 at the time of CPAP removal.

Table *Comparison of the Po_2 response subgroups*

	Increased ($n = 5$)	*Unchanged* ($n = 20$)	*Decreased* ($n = 5$)
Birthweight (mean ±SD g)	2240 ± 790	1805 ± 558	2080 ± 348
Age at start (hours)	6 ± 4	10 ± 8	16 ± 16
A-aDo_2 start (mmHg)	210 ± 90	238 ± 123	197 ± 70
Po_2 prior (mmHg)	57 ± 4*	67 ± 8	76 ± 4
Change in Pco_2 (mmHg)	−4 ± 6	−1 ± 5	3 ± 4

Conversion: traditional to SI units—A-aDo_2, Po_2, and Pco_2 1 mmHg ≈ 0·133 kPa.
*$P<0 \cdot 05$.

Discussion

Before this prospective trial, the procedure for stopping CPAP in the treatment of infants with RDS had not been critically assessed, although textbooks (Llewellyn and Swyer, 1973; Pierog and Ferrara, 1976) and papers (Krouskop *et al.*, 1975; Stark and Taeusch, 1977) have suggested that weaning is the optimal method of CPAP removal.

The results of this study show that the abrupt removal of CPAP did not place any infant in a state of hypoxia or hyperoxia. The possibility that the criteria for stopping CPAP resulted in some infants being treated longer than necessary is indicated by the correlations. The positive correlation between duration and Pco_2 before withdrawal as well as the negative one between Po_2 before withdrawal and the Po_2 response, suggest that towards the end of treatment CPAP may have had a deleterious effect. These results suggest that in some infants recovering from RDS, prolonged use of constant distending pressure can cause slight Po_2 decrease and CO_2 retention. This observation has previously been reported by Nelson *et al.* (1977). Therefore abrupt withdrawal could have been completed earlier in the course of recovery.

Several hypotheses may be considered as possible explanations for the blood-gas responses to CPAP withdrawal. The removal of a constant distending pressure may result in a new ventilation perfusion relationship or in the initiation of compensatory mechanisms by the infant.

We conclude that our population of infants recovering from moderate RDS tolerated the abrupt removal of CPAP, so that gradual reduction of pressure was unnecessary. In some infants prolonged use of CPAP had deleterious effects.

We thank Drs William Fox, Leonard Indyk, and L. Stanley James for suggestions, Mr John Kennedy for statistical analysis, and Mrs Nancy Gallo for secretarial assistance.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onwards all manuscripts submitted should accord with the new style.

Neonatal Society

Meeting held on 8 February 1979 at the Institute of Child Health, London

Prophylaxis of neonatal jaundice with maternal antipyrine treatment. L. Friedman and P. J. Lewis. Clinical Pharmacology Unit, Queen Charlotte's Maternity Hospital, London.

Neonatal jaundice is common and its incidence is thought to have increased recently. Both epidural anaesthesia and oxytocin administration during labour increase neonatal bilirubin concentrations (Friedman *et al.*, 1978). Neonatal jaundice results from immaturity of the hepatic enzyme system which glucuronates bilirubin. Glucuronidation may be induced in the fetus by exposure to inducing agents and phenobarbitone treatment of pregnant women has been shown to be effective in reducing neonatal jaundice. However, phenobarbitone is sedative and rarely used. Antipyrine, an antipyretic known to induce glucuronyl transferase in adults, is without sedative properties (Orme *et al.*, 1974).

Pregnant women were recruited during the 38th week of pregnancy and allocated at random and double blind to placebo or antipyrine (300 mg daily). Babies who satisfied the protocol were seen on the 4th day after birth and total serum bilirubin concentrations measured.

90 women were recruited; 48 completed the protocol, 24 in each group. The mean (± SEM) bilirubin concentration was $111\cdot5 \pm 13\cdot5$ µmol/l ($6\cdot5 \pm 0\cdot8$ mg/100 ml) on placebo and $62\cdot6 \pm 11\cdot2$ µmol/l ($3\cdot7 \pm 0\cdot6$ mg/100 ml) on antipyrine ($P<0\cdot005$). The mean birthweights were 3·419 kg on placebo and 3·432 kg on antipyrine. Mothers in both groups took an average of 15·5 tablets. No adverse effects were noted.

We suggest that brief perinatal exposure of the mature fetus to antipyrine reduces neonatal bilirubin concentrations. The mechanism is presumed to be induction of glucuronyl transferase in the fetal liver.

Follow-up study of babies exposed to betamethasone before birth. A. M. Butterfill and D. R. Harvey. Queen Charlotte's Maternity Hospital, London.

It has been shown that glucocorticoids given to mothers in premature labour can reduce the incidence of respiratory distress syndrome (RDS) in their babies, but animal experiments suggest that glucocorticoids may have adverse effects on growth and mental development which could outweigh the benefits. We therefore attempted to study the growth and development of 120 babies born during a controlled trial in which mothers in premature labour (at 26–37 weeks' gestation) received either betamethasone (4 mg 8-hourly × 6) or a placebo.

12 babies died, 6 from each group, and 3 were not traced. Limited information was available about 17 babies; one from the betamethasone group was severely retarded, but the others were thought to be normal. The remaining 88 children were examined once, in detail, between ages one and 4 years. The two groups (41 whose mothers received betamethasone and 47 controls) were well-matched for length of gestation (26–42 weeks), socioeconomic group, age at follow-up, and other perinatal and social factors which could affect development. There were 5 cases of RDS in the betamethasone group and 8 in the controls. At follow-up no child was developmentally retarded or suffered major handicap. Minor abnormalities and defects of vision and hearing were present equally in the two groups. There was no difference between the groups in height and weight. There was no difference in the general quotient of the Griffiths's Mental Development Scales, but the betamethasone group had lower scores on the performance scale (106, control 113, $P = 0\cdot05$).

Neurological examination of children who were small-for-dates babies. D. R. Harvey and S. M. Wallis. Queen Charlotte's Maternity Hospital, London.

Small-for-dates babies are more likely to have neurological abnormalities and learning problems in childhood than babies of normal birthweights (Dobbing *et al.*, 1971). There is evidence that animals are clumsy if their brain growth is impaired during a phase of development equivalent to that of the human brain in the latter half of pregnancy (Fitzhardinge and Steven, 1972; Neligan *et al.*, 1976).

We followed up a group of small-for-dates babies whose antenatal growth was documented with serial ultrasonic cephalometry. All were term, singleton births, with no significant neonatal problems. 20 of the children were selected for study; 10 had slow head growth starting before 26 weeks' menstrual age, and 10 had normal head growth before birth. The groups were matched for age and sex. They were seen at a mean age of 6 years and examined for evidence of minor neurological dysfunction using the technique described by Touwen and Prechtl (1970). Those children whose head growth began to slow before 26 weeks' menstrual age, had lower overall scores on neurological examination with impairment of co-ordination and balance. They also performed poorly in a test constructing matchstick shapes.

Validation of oesophageal balloon measurements in infants. C. S. Beardsmore, P. Helms, and J. Stocks. Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital, and Respiratory Unit, The Hospital for Sick Children, London.

Oesophageal balloons are often used to measure transpulmonary pressure changes in infants in order to calculate their pulmonary resistance (Rp) and dynamic compliance ($C_L$dyn). In adults, numerous problems associated with the use of oesophageal balloons have been reported, but little work has been done to validate the use of this technique in infants (Dinwiddie and Russell, 1972; Milner *et al.*, 1978). Previous work shows that measurements of Rp are considerably less accurate and less reproducible than those of airways resistance (Raw) measured by plethysmography (Stocks, 1977).

In an attempt to determine why these discrepancies occur, we performed detailed *in vitro* and *in vivo* experiments to assess which factor might affect the reliability of oesophageal balloon recordings. Variations in the dimensions, wall thickness, and volume of air within the balloons were all found to affect critically their pressure volume characteristics. These factors caused significant variations in the measured values of Rp and C_L obtained from individual babies.

Recommendations are made for the ideal internal working volume and physical characteristics of oesophageal balloons for the measurement of transpulmonary pressure changes in infants.

Blood pressure in the first 6 weeks of life. A. Earley, P. Fayers, and M. de Swiet. Department of Paediatrics, Cardiothoracic Institute, and MRC Tuberculosis and Chest Diseases Unit, Brompton Hospital, London.

Previous studies show that BP increases greatly at some time between ages 4 days and 6 weeks and then it remains constant until age 6 years (de Swiet *et al.*, 1976, 1979). However, the precise age at which this rise takes place is uncertain. Systolic BP has therefore been measured using the Parks Doppler system in 100 normal newborn infants, on alternate days during the first 10 days of life, and then at weekly intervals to age 6 weeks.

BP rose from 68 ± 11 mmHg at 2 days to 78 ± 12 mmHg at 6 weeks (after adjustment for level of consciousness). However, most of this rise (9 mmHg) took place during the first 14 days.

If, as has been suggested from animal studies (Klopfenstein and Rudolph, 1978), the cardiac output/kg body weight decreases in the first 6 weeks of life, then the concurrent rise in BP indicates that peripheral vascular resistance increases very markedly in the neonatal period.

Aspects of perinatal transcutaneous Po_2 monitoring. F. E. Hytten and M. O'Connor (introduced by I. R. McFadyen). Division of Perinatal Medicine, Clinical Research Centre, Northwick Park Hospital, Middlesex.

A preliminary series of fetal intrapartum applications of the Draeger Transoxode is reported. 23 primigravidea and 7 multiparae were studied for periods ranging from 30 minutes to 12 hours (mean 3·8 hours). Two-thirds of patients had lumbar epidural analgesia before application of the electrode at a cervical dilatation of at least 4 cm (mean 6·4).

In 9 infants, modifications to the Huch technique of intrapartum application allowed us to record fetal transcutaneous Po_2 ($FtcPo_2$) both during delivery and for a maximum of 25 minutes postnatally.

Comparisons were made between the $FtcPo_2$ and the Po_2 in fetal scalp blood samples in 26 instances, and with umbilical arterial Po_2 in 12 cases where the electrode remained in place until delivery. The correlation with Po_2 in fetal blood samples shows a mean 27·5% underestimation by the $TcPo_2$ technique. However the reliability of measuring true Pao_2 using the Saling technique must remain in doubt. The correlation with cord artery Po_2 was also poor, $TcPo_2$ values frequently underestimating systemic arterial Po_2. Factors such as local scalp circulatory stasis, the 'diving reflex', and pressure effects on the Transoxode may be responsible for the poor correlations at this stage.

Normal levels in uncomplicated labours are being evaluated. It is hoped then to proceed with correlations between $FtcPo_2$ and other parameters indicating fetal distress.

Increased concentrations of hypoxanthine and xanthine in meconium-stained amniotic fluid. R. A. Harkness, R. J. Simmonds, M. O'Connor, and F. E. Hytten. Division of Perinatal Medicine, Clinical Research Centre, Northwick Park Hospital, Middlesex.

Meconium staining of amniotic fluid is used as an indication of fetal distress. We found that concentrations of the oxypurines, hypoxanthine and xanthine, in meconium-stained amniotic fluid are generally higher than in 'normal' amniotic fluid at 38–40 weeks' gestation, both sets of samples being from patients who were not in labour. These increases cannot be directly due to meconium, since hypoxanthine and xanthine concentrations in meconium were similar to those in amniotic fluid. The concentration of urate in meconium-stained amniotic fluid was not raised and that of uridine did not show a clear increase. Serial estimations of hypoxanthine and xanthine in amniotic fluid showed that there is a tendency for concentrations to rise during labour.

The basis for this investigation was that failure to maintain intracellular ATP concentrations is associated with release of hypoxanthine into extracellular fluid. The usual cause of such failure is hypoxia. Therefore estimates of hypoxanthine in extracellular fluids could provide a cumulative measure of hypoxic damage. The increase in concentrations of hypoxanthine and xanthine in the extracellular amniotic fluid when it is meconium-stained suggests this probably occurs in the perinatal period. The results support the hypothesis that fetal hypoxia has occurred in pregnancies with meconium-stained amniotic fluid.

Studies of fetal motor activity in the 3rd trimester of pregnancy. S. Campbell, K. T. Hertogs, A. B. Roberts, and S. M. Stubbs (introduced by H. J. Shelley). Department of Obstetrics and Gynaecology, King's College Hospital, London.

Fetal motor activity was assessed by real time ultrasound scanning. All observed movements were punched directly on to computer tape. The beginning and end of each movement was recorded so as to measure the amount of time the fetus was moving in each obervation period. The number of fetal movements was also calculated and expressed as the mean/30-min observation period.

In 20 pregnant women of 32–42 weeks' gestation, the 4 components of fetal motor activity (head, trunk, arms, legs) were each computed, using two real time scanners, and correlated with the maternal subjective assessment of fetal activity. It was established that fetal trunk movements (FTM) correlated strongly with total fetal motor activity, especially in those movements described as major. Thus FTM could be used to establish normal parameters of fetal motor activity in the 3rd trimester.

In 21 normal pregnancies 24-hour profiles were obtained, by recording for 1 hour in 3, providing a total of 168 hours for analysis. The mean percentage incidence of FTM was 18%, with a mean of 29 moves/30-min observation period. There was a well-defined circadian variation (day/night = 16/22%) which was the reverse of that for fetal respiratory movements (day/night = 37/23%). The variation in both parameters was wide but the total activity (breathing plus FTM) rarely fell below 10% in any 30-min study period.

Cross-sectional day-time data from 100 normal pregnancies between 28 weeks' gestation and term suggest that the mean number of moves/30-min period was inversely related to gestational age, although the percentage incidence of FTM (mean ± SD = 18 ± 10%) was constant throughout the 3rd trimester.

FTM was also studied in 20 pregnancies complicated by intrauterine growth retardation and 25 pregnancies complicated by maternal diabetes mellitus. Preliminary data from the latter group suggest that maternal hypoglycaemia may stimulate fetal motor activity.

Correspondence

Epididymo-orchitis in Kawasaki disease

Sir,

We were interested to read the report by Morgan and Lynch of a case of Kawasaki disease (*Archives*, 1978, **53**, 916). We wish to report a hitherto unrecorded finding occurring during the course of this condition.

A 6-year-old boy was admitted to hospital because of a possible abscess in the left posterior cervical area. He had a pyrexia of 38·5°C. A confluent erythematous rash was present on his trunk and limbs, being more pronounced on the palms and soles. The left testis was slightly tender and enlarged. He had a strawberry tongue, and the veins of the bulbar conjunctiva were noted to be very prominent. The temperature returned to normal after 5 days and he then developed pain and swelling of the right wrist. At the same time there was a striking desquamation of the skin on the palmar aspect of his finger tips. The nail bed was not affected. The testicular tenderness which had been noted on admission became more marked during the next 3 days. Both testicle and epididymis became moderately enlarged. The skin of the scrotum was red and mildly oedematous. Symptomatic treatment only was offered, and after a week the testis and epididymis had returned to normal. At follow-up 6 weeks later no physical abnormalities were present.

This case fulfils the main criteria for diagnosis of Kawasaki disease suggested by Tanaka *et al.* (1976). There have been some less common associated findings in this condition. One of these is sterile leucocyturia, which was present in our case. It is almost certain that this is due to urethritis, as suprapubic aspiration carried out in the presence of pyuria in a number of these cases has shown normal bladder urine (Melish *et al.*, 1976). However, testicular involvement has not thus far been described. It is likely that the inflammation in our case started in the urethra and progressed via the vas to involve the epididymis and testis.

Blood lead level survey

Sir,

In response to concern about possible lead pollution due to heavy traffic on a narrow eastern part of the A2 in Greenwich (Rochester Way) a small survey of the blood lead levels in preschool children living on or near the route was undertaken in October 1978. This concern had not been alleviated by the knowledge that an estimation of lead in air at this point, based on detailed studies of kerbside pollution from motor vehicles in 5 cities—including London, was between 2 and 4 μg/m^3, probably in the lower half of this range. The GLC guideline for air quality is 3 μg/m^3 (lead in suspension) over a 3-month period (Greater London Council, 1975). Topographical and traffic analysis showed that this road carried 35 000 slow-moving vehicles a day, 30% of them using diesel fuel, and many of them being of the heavy goods type. The widths of the carriageway and street were 8 and 24 m respectively, the flanking houses being of two storeys, and the road direction being east to west with a one in 40 upwards gradient towards the east.

41 children were chosen from health visitors' records and eventually 35 of them attended a clinic for venepuncture. One child withdrew before the test, and the test on one other child was abandoned for technical reasons. Analyses on these 33 blood samples were carried out at the department of chemical pathology at Great Ormond Street Children's Hospital. Subsequently another child, absent on holiday, gave a sample of blood which was tested at the chemical pathology department of the Brook Hospital laboratory.

The overall geometric mean of these results was 16·3 μg/100 ml, on a near-normal distribution, the highest reading recorded being 26·9 μg/100 ml. The normal reference range of the EEC directive on biological screening for lead is 0·3–1·8 mmol/l (approximately 6 to 37 μg/100 ml) and by this standard the levels were considered to be satisfactory. It is of interest that this mean differs only slightly from the mean of 15 μg/100 ml used by the Environment Protection Agency in the United States for setting a national ambient air quality standard for lead (final results and proposed rule making, October 1978).

There are slight variations near the mean for the subgroups and these are set out in the Table, the actual numbers being given in parentheses for each group.

These results have been interpreted as natural variations without any pattern or relationship to age, site, or residence, and there is no suggestion of statistical significance about them. There is an overlap of the 95% confidence limits for another value between the various groups in the Table. The children had lived on Rochester Way long enough to have absorbed any lead from vehicle exhausts and for it to have been fully reflected in their blood lead readings. There was no evidence of ill health attributable to the ingestion of lead among the children examined by the medical officer at the school. It was concluded that, whatever undesirable effects of traffic there may be on Rochester Way, the inclusion among them of lead pollution was not supported.

Table *Blood lead levels in 33 children*

Mean result (μg/100 ml)	*Average age*		*Average length of residence*	
	Years	*Months*	*Years*	*Months*
Children attending a nursery school on Rochester Way and living on Rochester Way (n = 2)				
19·7	4	8	3	1
Children attending a nursery school on Rochester Way and living off Rochester Way (n = 4)				
17·2	4	11	4	5
Children living on Rochester Way west of Well Hall roundabout (n = 11)				
17·6	3	3	2	5
Children living on Rochester Way east of Well Hall roundabout† *(n = 11)*				
15·1	2	5	2	3
*Children living near Rochester Way (n = 5)**				
17·8	2	7	2	5

*The child (aged 6 years) tested at the Brook Hospital laboratory, living near Rochester Way, had a blood level of 18·6 μg/100 ml.

†8 of these children lived on the narrow part of the road and their mean result was 15·1 μg/100 ml, their average age being 2 years 7 months with an average length of residence of 2 years 4 months.

Not far away, preschool children in another recent survey carried out near a lead smelter were found to have a mean level of 21 μg/100 ml (Millar, 1978).

It is important at this present time to be clear about the biological relationships with lead in the environment. Lead at low levels in blood is being associated with malfunctions which on the evidence are as likely to have other parallel and independent associations. At these levels blood lead variations would reflect environmental variations and all the differences could be significant, yet without dysfunction of any kind, or with dysfunctions otherwise explained. On the other hand, the practice of environmental evaluation and lead hazard abatement near and above the upper end of the EEC reference range is clearly indicated (Center for Disease Control, 1978).

Cefuroxime plasma and CSF levels in children with meningitis

Sir,

Kuzemko and Walker recently reported their experience with cefuroxime in meningitis (*Archives*, 1979, **54**, 235).

We gave cefuroxime to 17 patients aged between one month and 10 years. Six of them had meningitis, the others had severe pneumonia or laryngitis. The patients with meningitis were initially treated with ampicillin, chloramphenicol, or a combination of ampicillin and gentamicin. Cefuroxime was given before the final lumbar puncture when the patient had recovered, generally after 8 days of treatment. Cefuroxime 25 mg/kg was given intravenously by 30-min infusion every 6 hours. The organisms responsible for the meningitis in 3 patients were *Neisseria meningitidis*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*. In the other 3 patients with meningitis the organism could not be identified because the patients had been treated with antibiotics before admission to hospital. In the patient with *N.meningitidis*, the MIC for cefuroxime was <0·03 μg/ml. Lumbar puncture was performed 30 to 120 minutes after the end of the infusion by which time the child had received cefuroxime treatment for 24 hours. At that time, blood samples were taken 4 or 5 times from 30 to 180 minutes after the end of the infusion by an indwelling IV catheter at a site different from that of the infusion.

The resistance of *Klebsiella* to other antibiotics in a child with ventriculitis and meningomyelocele led to treatment being increased from 25 mg cefuroxime every 4 hours to 50 mg every 4 hours. The presence of an indwelling intraventricular reservoir allowed the level of the drug to be estimated in the ventricular fluid after the intravenous administration, and later after parenteral and 10 mg intraventricular administration.

All samples were assayed biologically. Adequate plasma cefuroxime concentrations ranging from 23 to 115 μg/ml were obtained throughout. The concentration in the spinal fluid (Figure) ranged from 0·2 to 1·2 μg/ml with a dosage of 25 mg/kg 6-hourly. In the child with ventriculitis, ventricular fluid concentrations were between 3·6 to 7·6 μg/ml with 25 mg/kg 4-hourly, and 16·8 μg/ml with 50 mg/kg 4-hourly; intraventricular administration resulted in very high concentrations of 26 μg/ml on the left side and 89 μg/ml on the right. The higher values found in the patient with ventriculitis are presumably due to the better penetration of the drug through the inflamed meninges. No toxic side effects were observed. These results corroborate the findings of Kuzemko and Walker.

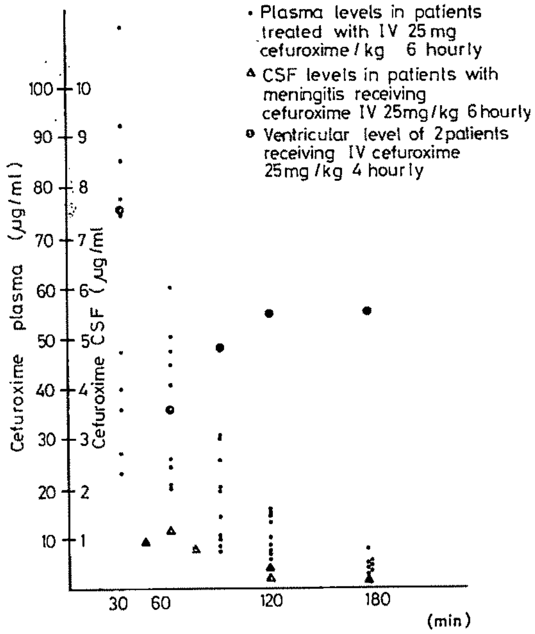

Figure *Plasma and CSF levels of cefuroxime (min) in children with meningitis or other infections.*

A cefuroxime dosage of at least 25 mg/kg 4-hourly seems suitable and should be adapted according to the MIC of the micro-organism and the level of the drug in the CSF.

We thank Mr W. Ryngaert of Glaxo, Belgium for the cefuroxime supply.

ook reviews

etus into Man: Physical Growth from onception to Maturity. By J. M. Tanner. p. 250; illustrated + tables. £7·95 hard-ck, £4·50 paperback.) Open Books: ondon. 1978.

o describe the physical growth and evelopment of children in a manner that stimulating to the biologist and the non-chnical general reader alike, must have een a difficult undertaking but the author as succeeded magnificently. The subject atter is at the crossroads of many isciplines, thus requiring a broadly-based pproach. There are chapters not only on tal growth, sexual differentiation, the rowth curve and puberty, but also on llular mechanisms, tissue and organ rowth, and the relevant endocrinology. However, there is total coherence, and veral themes, including reference to arwinian theory, recur throughout.

Perhaps the best chapter is that on the nteraction of heredity and environment in e control of growth, for which data have een carefully selected and interestingly nalysed, with emphasis on the problem f malnutrition. For paediatricians, the hapters on puberty, early and late aturation, and standards of normal rowth, are of great practical importance; clear outline of the normal variations of ubertal development is useful. I wonered if a more specific reference should ave been made to the possible role of the ineal gland in the control of the onset of uberty, but it is inevitable that the more pecialised reader will complain that a articular section was not expanded and at he will disagree with some points of nterpretation. However, he will be ducated by finding those concepts with hich he is familiar set in a much wider ontext.

All readers will find themselves drawn rom one chapter to the next by fascinating ems of information which make the ook so readable. For example—did you now that, in one study, shorter girls more ften married men in manual jobs, that e correlation between dental and bone ge at a given chronological age is only ·4, that the shape of the human growth urve is shared only by other primates, nd that boys in certain boarding schools grew more poorly during term than in the holidays? In the closing chapters an outline is briefly given on some clinical growth disorders and, at considerable length, a 'do-it-yourself' kit is produced for parents, teachers, and health visitors to enable them to estimate the ultimate height of a child and to determine whether growth is normal. Once more the author attempts, for the best of reasons, to seduce us from the Gregorian to the Tannerian decimal calendar!

It is a short book of some 250 pages, tightly argued, lucidly written, comprehensively illustrated, and with an excellent bibliography. Professor Tanner, uniquely qualified to write such a book by the outstanding contributions he has made to the study of human growth and to child health, has produced an account which is compulsive reading for the paediatrician and which should be compulsory reading for the medical student.

D. A. PRICE

Human Growth: volume 1, Principles and Prenatal Growth; volume 2, Postnatal Growth. Edited by F. Falkner and J. M. Tanner. (Pp. 634 each volume; illustrated + tables. £24·75 each volume, hardback.) Baillière Tindall: London. 1979.

These are the first two volumes of a 3-volume comprehensive textbook about human growth from conception to adult life edited by 2 well-known authorities, one from each side of the Atlantic. Of the 21 chapters in vol. 1, 4 are about developmental biology including changes with age in biochemical constitution and the way the body handles drugs, 3 consider the methodology of growth studies, 4 are on the genetics of biochemical, intrauterine, and postnatal growth, and the rest are about aspects of intrauterine growth including the placenta. Vol. 2 is concerned with postnatal growth. It begins with chapters on cellular growth and on measuring techniques. These are followed by chapters on the pattern and control of growth before and during puberty, and a series on the growth of individual tissues including muscle, fat, bone, and teeth. Rather surprisingly the book ends with 2 chapters about low birthweight babies.

Each chapter is written by a different author, altogether in the three volumes over 60 from 10 countries. This leads to wide variations in style and aims; some chapters are very detailed reviews with many references—for example those on biochemical development and perinatal endocrinology—while others are less comprehensive; some present new information, but a few chapters are poor, unintelligible, or boring. Although variation is good, it is a pity that some chapters do not have a summary, that some subjects —for example the effect of smoking in pregnancy and the maternal deprivation syndrome—have slipped between chapters and almost disappeared, and that the index which is large is not more comprehensive. But the books are pleasing, of reasonable size, and well produced and illustrated. As a series of essays related to growth, they are fascinating and instructive. If you want to know why the newborn hippopotamus is larger than the newborn human baby, or the effects of swimming on bone age, or the male/female ratio for lean body mass, or thousands of other facts not easy to find elsewhere, these books will help.

But are they needed? The great interest in the biology of human growth during the last decade has led to a massive increase in knowledge and there is a place for such a scholarly and detailed review of the subject for the clinician and the scientist concerned with the growing human being. Unfortunately the importance of growth makes it a subject with long tentacles and a book like this that aims to be comprehensive must be huge and expensive, and will both overlap greatly with other books dealing with the basic science of childhood and be incomplete. Nevertheless this will be a useful reference book and at least deserves a place in university and paediatric departmental libraries.

The third volume is now available and shares the strengths and weaknesses of the other. It is devoted to neurobiology, with a wide ranging series of chapters on the development of the brain and the relationship between this and behaviour; the effects of variations of nutrition upon growth;

and a final scholarly chapter on the history of growth studies.

J. M. PARKIN

Maternal Nutrition and Child Health. By D. R. Shanklin and J. Hodin. (Pp. 205; illustrated + tables. $14·75 hardback.) Thomas: Springfield. 1979.

Whether maternal nutrition during pregnancy and lactation has any effect that matters on fetal growth and postnatal development remains a subject for serious debate. No one disputes the fact that birthweights are reduced by about 10% during acute severe famine (although a fall in birth rate is more noticeable), or that maternal dietary supplementation can raise birthweights by a similar amount in chronically undernourished populations. The argument is whether it matters, and ranges between those for whom the birthweight deficit corresponds to an unimportant deprivation of the luxury of subcutaneous fat, at one extreme, and those who rather vaguely suspect that it may in some way affect brain growth and hence the intellect, at the other. Those of us in relatively affluent countries are additionally faced with the question whether the preponderance of small-for-dates babies in the less privileged social classes may be partly due to an unbalanced maternal diet as well as to smoking, teenage pregnancy, and other correlates of indigence or social delinquency. The answer is by no means clear, and becomes considerably less so when attempts are made to relate disturbances of later child behaviour to smallness-for-dates at birth in babies of undernourished mothers. The myriad of inevitable and interrelated components of poverty and undernutrition defy analysis as causal factors in the genesis of performance deficits among the child victims of such society, so that it will probably never be possible to dissect the nutritional factors away from the remainder, all of which are powerful determinants of substandard human achievement. By the same token, attending to the nutritional deficits in isolation is unlikely to resolve many problems, although some good might accrue where they are severe.

For some of our colleagues, however, the matter is not nearly so complicated. The authors of this book tell us without ambiguity that 'the relationship between nutrition, especially during the prenatal period, and child mental and physical health is demonstrated to be causal and highly correlated' (sic). Some of the studies indicate that there is less than one chance in a billion that prenatal nutrition does not influence the newborn's health and subsequent mental and physical development. In addition, they say, warming to their theme, 'neurological abnormalities, such as mental retardation, cerebral palsy, and epilepsy, which have traditionally been ascribed basically to genetics or unknown causes, are linked in large part to malnutrition during the most rapid, critical periods of development. A continuum of reproductive casualty, defined as spontaneous abortion, perinatal death, cerebral palsy, epilepsy, mental retardation, hyperkinesis/learning disabilities, and minor neurological disorders, can be caused by varying degrees of prenatal malnutrition'.

The rest of the book contains a highly selected, often misinterpreted, and tediously repetitive review of the literature; and those, like your reviewer, who have been endlessly bombarded with communications from Tom Brewer and the Society for the Protection of the Unborn through Nutrition (SPUN) in spite of begging him to desist, will not be surprised to find in the Foreword that 'the scientific studies reviewed in this work represent the basis for his efforts'. One of the authors turns out to be Executive Director of SPUN.

It would all be good knockout stuff if it were not likely to be taken seriously by the 'allied health professionals' and the senators on Brewer's mailing list, and by other influential people who are without sufficient familiarity with the subject to put the book firmly where it belongs.

JOHN DOBBING

Ultrasound in Pediatrics. Edited by M. Miskin. (Pp. 337: illustrated + tables. $29·50.) Grune and Stratton: New York. 1979.

Ultrasound provides medicine with a unique noninvasive method of investigation. Unlike other imaging techniques using *x*-rays it is without radiation hazard.

Ultrasound has made a great impact on obstetrics and it was hoped would be as useful in paediatrics. Unfortunately for children, paediatricians have been slow to accept and to press for its use. Part of the blame lies in the lack of information on the use of ultrasound in children. For this reason the publication of this book welcome. It may make those dealing w sick children aware of what may be mi ing from their own armoury of investi tions.

However the book is not enti relevant to the development of paediat ultrasound in Europe. There are obvio regional differences in the definition paediatrics. European doctors might r accept alcoholic pancreatitis and caesare section scar haematomas as being partic larly paediatric problems.

Half of the book is devoted to a fasc ating account of cranial ultrasound whi is compared with pneumoencepha graphy. The authors are obviously ve experienced but computerised axial tom graphy has now become so well establish as the method of cranial examination th the lack of comparison of ultrasound w CAT will leave readers sceptical of value.

There follows a short, useful, we referenced introduction to echocardi graphy, but with only a passing comme on real time scanning.

Almost one-third of the book is left cover the abdomen and pelvis. Consideri the experience and reputation of t authors, the images are only medioc the text contains many factual errors a is not critical enough of the relative u fulness of ultrasound. However, t '*Reader's Digest* style' makes it an ea introduction to this topic and interesti reading despite the irrelevancies a errors.

C. METREVEI

Shorter notice

Smith's Blood Diseases of Infancy a Childhood, fourth edition. Edited D. R. Miller, H. A. Pearson, R. Baehner, and C. W. McMillan. (Pp. 88 illustrated + tables. £34·00 hardback Mosby: St Louis. 1978.

The original textbook of pediatric haem tology has, inevitably, in this, its 4 edition become a multiauthor book. T editors manage to combine basic physi logy (for example of erythropoiesis ar haemolysis) with comprehensive clinic coverage (as in the excellent chapter iron metabolism). The result is surprising readable and up to date and, despite t price, must be the best buy for a depar mental library.

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Phadebas RAST®

In-vitro test for atopic allergy.

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

from January 1 1979

Archives of Disease in Childhood

will be available to junior doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following subscription rates apply for the twelve issues published in 1979.

Inland £17.00

Overseas US$40.00

(The full rates are: Inland £28.00; Overseas US$65.50)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42,** 109: 1973, **48,** 751; 1978, **53,** 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1**, 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Multiple copying of the contents of the publication without permission is always illegal.

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Contents

Immunologic and Clinical Investigation on a Bovine Thymic Extract. Therapeutic Applications in Primary Immunodeficiencies 797

F. Aiuti, P. Ammirati, M. Fiorilli, R. D'Amelio, F. Franchi, and L. Businco (Rome, Italy)

Clinical and immunologic studies observed after thymostimulin treatment in immunodeficient patients are described in this paper.

Effect of Thymic Humoral Factor on Cellular Immune Functions of Normal Children and of Pediatric Patients with Ataxia Telangiectasia and Down's Syndrome........ 803

Z. T. Hanzel, Z. Dolfin, S. Levin, Y. Altman, T. Hahn, N. Trainin, and N. Gadot (Beer-Sheva, Israel)

The effect of thymic humoral factors on cellular immune function was evaluated in nine patients with Down's Syndrome and nine with Ataxia Telangiectasia using *in vitro* assays.

Ornithine Transcarbamylase Deficiency in Mutant Mice. I. Studies on the Characterization of Enzyme Defect and Suitability as Animal Model of Human Disease 807

I. A. Qureshi, J. Letarte, and R. Ouellet (Montreal, Quebec, Canada)

Kinetic studies were conducted on liver ornithine transcarbamylase from sparse-fur (spf) gene bearing mice to characterize the enzyme defect; urinary orotic acid was measured to study the suitability of mutant mice as animal models for hereditary hyperammonemia in children.

Favism in $\mathrm{Gd}^{\mathrm{Mediterranean}}$ Heterozygous Females 811

G. Sanna, S. De Virgillis, C. Palmas, F. Argiolu, F. Frau, and A. Cao (Sardinia, Italy)

These authors establish the levels of G6PD activity and the percent of deficient red cells in female heterozygotes for G6PD deficiency of the $\mathrm{Gd}^{\mathrm{Mediterranean}}$ type.

Postnatal Development of Renin-Angiotensin-Aldosterone System/RAAS/In Relation to Electrolyte Balance in Premature Infants 817

E. Sulyok, M. Nemeth, I. Tenyi, I. Csaba, E. Gyory, T. Ertl, and F. Varga (Pecs, Hungary)

In order to obtain information about the role of the renin-angiotensin-aldosterone system in the development of hyponatraemia, this study was performed to determine the postnatal changes of plasma renin activity, plasma aldosterone concentration, and urinary aldosterone excretion in relation to the electrolyte balance in premature infants during the first 6 wk of life.

In Vivo Evaluation of Monopolar Intravascular PO_2 Electrodes 821

A. V. Beran, G. Y. Shigezawa, D. A. Whiteside, H. N. Yeung, and R. F. Huxtable (Irvine, California)

An intravascular electrode system for the measurement of PO_2 was evaluated for its stability, drift, need for recalibration, and blood compatibility.

Hyperargininemia with Arginase Deficiency 827

S. D. Cederbaum, K. N. F. Shaw, E. B. Spector, M. A. Verity, P. J. Snodgrass, and G. I. Sugarman (Los Angeles, California and Indianapolis, Indiana)

These scientists document the deficiency of arginase in white blood cells and liver in two siblings of Mexican origin and report abnormal levels of 15 amino acids in their cerebrospinal fluid. This finding suggests a general perturbation in amino acid homeostasis in these patients.

Increased Heparin Binding in Cystic Fibrosis: A Reflection of Altered Glycoprotein Biosynthesis? 834

R. D. Pearson and A. H. Lubin (Columbus, Ohio)

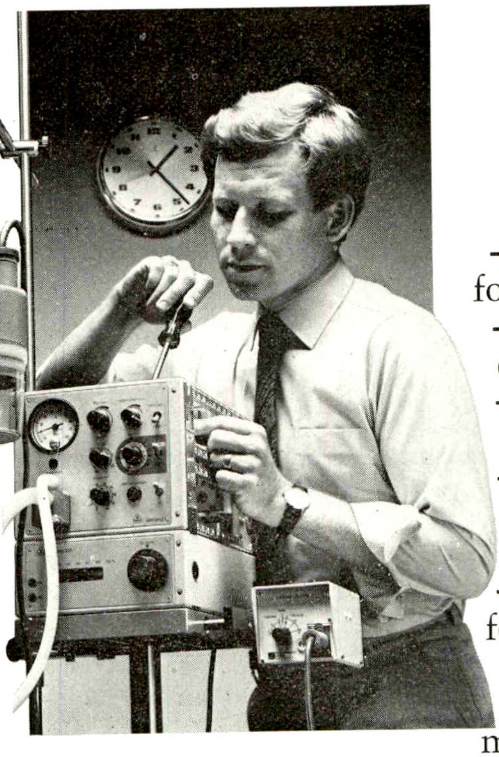
Results of this study suggest that glycoproteins of abnormal carbohydrate composition are responsible for the increased "heparin binding capacity" of serum proteins in cystic fibrosis.

Maternal Fetal Osmolar Homeostasis: Fetal Posterior Pituitary Autonomy........ 841

R. D. Leake, R. E. Weitzman, R. M. Effros, S. R. Siegel, and D. A. Fisher (Torrance, California)

Arginine vasopressin secretion was assessed in fetal lambs in response to maternal osmolar stimuli and compared with similar stimuli in newborn and adult lambs.

If your department worked a 5 day week, so would we.



Draeger service:
und the clock, round
e year.

Our service epartment is rganised in the elief that working for ospitals is a matter of fe or death.

So we maintain an mergency service – with ull parts back up – in very part of Britain.

We don't expect to be alled out too often, ecause if there's one hing Draeger equipment s noted for, it's reliability.

And it's especially eliable when maintained by our service team under a contract maintenance programme. (Details of which we'll send if you ask.)

Draeger service covers a whole range of equipment:–

— the Babylog ventilator for neonates;
— the UV1 ventilator for children and adults;
— Incubators and the Babytherm;
— Aseptor disinfecting units and a range of washin and drying equipment;
— the Draeger Oxymeter for the non-invasive measurement of blood gas levels;
— and Draeger anaesthetic machines and piped medical gas installations.

Draeger service, round the clock, round the year, could be the most vital reason of all for choosing Draeger equipment.

Epilepsies of Childhood

NIALL V. O'DONOHOE, MD, FRCP(I), DCH

Postgraduate Paediatrics Series

General Editor: John Apley

A chronological description of aspects of the various childhood epilepsies from the neonatal period through infancy to adolescence. The emphasis is on clinical aspects, on the importance of accurate and differential diagnosis of epilepsy, on treatment and on prognosis. Particular attention is given to the emotional and psychiatric aspect of the disease, and to the enormous increase in medical knowledge of these conditions which has taken place in recent years.

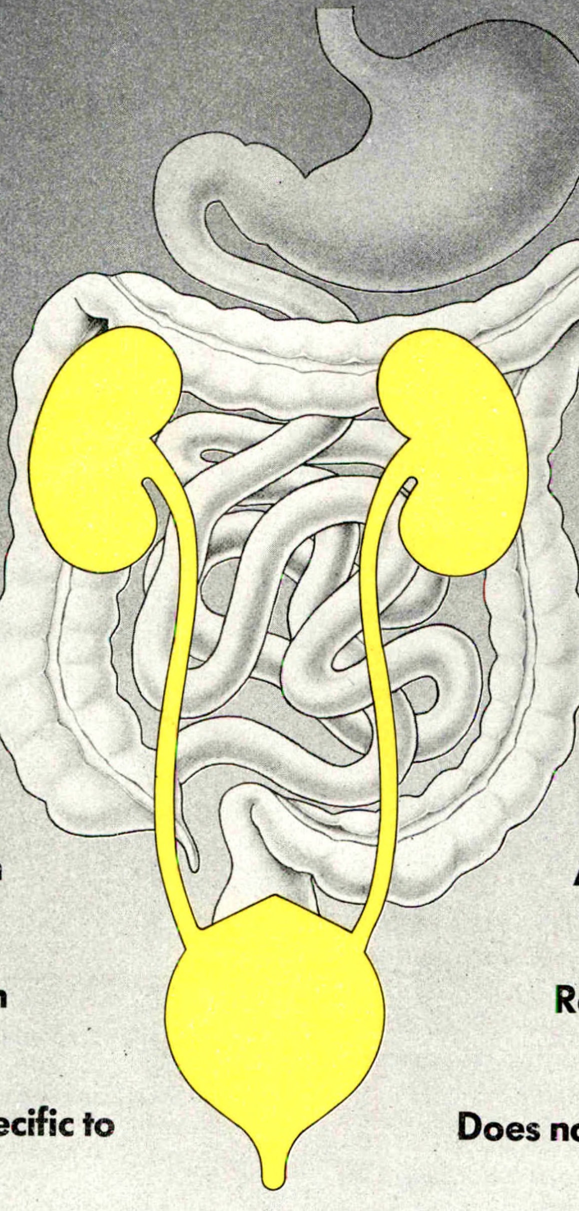
Furadantin Suspension

(nitrofurantoin)

To prevent lower urinary tract reinfection in childhood*



The only liquid form of nitrofurantoin.

For recurrent U.T.I. in childhood.

Bactericidal and specific to urinary tract.

Active in both urine and renal medulla.

Rapidly absorbed in G.I. tract.

Does not cause changes in gut flora.

Prescribing Information

Presentation Furadantin Suspension contains 25mg nitrofurantoin in each 5ml.

Action Furandantin Suspension contains nitrofurantoin, a broad spectrum antibacterial agent, bactericidal in renal tissue and throughout the urinary tract. After oral administration the nitrofurantoin is rapidly excreted in the urine, up to 45% being unchanged.

Uses Therapeutic. Cystitis, pyelitis, pyelonephritis; also post-operative infections of the genito-urinary tract, particularly after the passage of instruments and after prostatectomy. Furadantin Suspension is indicated in the treatment of urinary tract infections in pregnancy. The active ingredient, nitrofurantoin, has been in widespread use for over 23 years; this extensive clinical experience, and foetal studies in animals, have shown no evidence to suggest that nitrofurantoin may be a cause of congenital abnormality. However, it is recognised that caution should always be observed when prescribing for the pregnant patient.

Prophylactic. To prevent reinfection in susceptible individuals. As cover for catheterisation or instrumentation of the urinary tract.

Administration Furadantin Suspension is administered orally. The dose should be taken with each meal and at bedtime with food or milk.

Dosage Therapeutic. Adults 20ml 4 times daily.

Children

Bodyweight		Average age for weight	Dose to be taken 4 times a day
lb	kg		
10-30	5-13	3-30 months	2.5ml
30-50	13-23	2½-6 years	5ml
50-80	23-36	6-11 years	10ml
80-110	36-50	11-14 years	15ml

Prophylactic. One quarter to one half of therapeutic dose.

Contra-indications Infants under one month should not be given nitrofurantoin. Contra-indicated in patients suffering from severe renal impairment.

Side-effects and precautions Glucose-6-phosphate dehydrogenase deficiency. Peripheral neuropathy has rarely been reported after treatment with nitrofurantoin. Should numbness or tingling occur in any part of the body, treatment should be discontinued.

Nausea or vomiting may occasionally occur but this can be minimized or eliminated by taking the drug with food or milk, or reducing the dosage, but not below the adult equivalent of 200mg in 24 hours. Drug rashes and pyrexia with nitrofurantoin therapy have occasionally been reported.

Rarely a respiratory syndrome with bronchospasm and/or dyspnoea, cough and sometimes chest pain has been reported. These symptoms have occasionally been associated with transitory pulmonary infiltration or pleural effusion. Rarely, nitrofurantoin has been shown to cause hepatotoxicity.

Packaging Furadantin Suspension is supplied in bottles of 300ml.

Basic NHS cost 300ml bottle £2.18.

'Furadantin' is a registered trade mark.

PL 0364/0010 PA 170/5/3

Full information is available on request.

Eaton Laboratories, Regent House, The Broadway
Woking, Surrey GU21 5AP.

Annotation

Human growth hormone (UK)

Human growth hormone manufactured in the United Kingdom (GH (UK)) has been available since 1959 for the treatment of patients suffering from growth hormone deficiency. At that time a Working Party of the Pituitary Hormone Committee of the MRC was formed to design and carry out a clinical trial of GH (UK) as a growth promoting agent in patients of short stature. Favourable therapeutic results led to extension of the trial from simple assessment of the efficacy of GH (UK) to more detailed studies of the best mode of usage. From being a purely research exercise in the early 1960s the emphasis of the Working Party's remit shifted gradually to a service commitment to provide GH treatment for those who need and can benefit from it. This led to the development of a national system for the evaluation and treatment of patients suffering from lack of GH and in 1977 responsibility for the provision of treatment with GH (UK) transferred from the MRC to the DHSS. The experience accrued by the MRC Working Party has recently been published.[1] A Health Services Human Growth Hormone Committee (HSHGHC) was created by the DHSS to replace the MRC Working Party and in announcing this the department commented[2] '. . .The demand for hGH and the supply from pituitaries are fairly finely balanced and are expected to continue to be so in future. . . .It is likely that treatment with hGH will for some years be regarded as a new and developing service and paediatricians with experience and expertise in this specialised area will tend to be those who have been associated with the MRC trial and the growth assessment centres. Moreover, given the limited availability of hGH it is important that broadly uniform clinical criteria are applied in the selection of patients and the determination of therapeutic regimens.'

Today there are 19 growth assessment centres in the UK at which patients are measured and the effects of treatment monitored. Allocation of GH (UK) is decided by the HSHGHC quarterly on the basis of application by the physician in charge of the patient. An integral part of the application is the anthropometric information provided by the growth assessment centre. The HSHGHC has a co-ordinator who is responsible for collating information from the centres and sending GH (UK) to them for distribution to the patients.

GH (UK) has been extracted at the Department of Biochemistry, University of Cambridge since the beginning of the MRC trial using acetone-preserved pituitary glands as starting material. The GH (UK) prepared in this way has been shown to be therapeutically effective and free from side effects over 17 years with the exception of a few patients (less than 2%) who develop growth inhibiting antibodies. The preparation is known not to be homogenous protein and to contain large molecular weight components inferred to be aggregated GH and small but detectable concentrations of other pituitary hormones when tested by immunoassay.[1] Other methods of pituitary preservation and growth hormone extraction have been studied in an attempt to obtain a purer product. GH (UK) has been prepared from frozen glands at St Bartholomew's Hospital, London and used successfully in the treatment of certain patients who had developed growth inhibiting antibodies to conventional therapy with GH (UK). Commercial therapeutic GH is also prepared from frozen glands. The relative advantage of preserving pituitary glands in acetone or by freezing is not obvious. Freezing is less damaging to the peptide hormones in the pituitary but may also result in the preservation of other contaminants among which viruses are a remote but particular cause of concern. The logistics of preserving and transporting frozen glands nationally is more difficult than for acetone-preserved glands. After considering all the factors carefully, the department has made plans for the future production of GH (UK), initially from acetone-preserved glands using a modified extraction procedure which includes additional steps to remove high molecular weight aggregated and contaminating hormones. Arrangements have been made to transfer production to the Centre for Applied Microbiological Research at Porton Down which should begin to supply GH (UK) at the end of 1979. A research and development programme will operate concurrently at Porton which will include other methods of production.

An important argument against using GH from commercial sources overseas is cost, but even more important is the question of supply. Industry could not provide the quantity of GH needed in the UK from existing stocks and would have to rely on the provision of pituitaries collected in the UK for hormone extraction. The processing of the glands by the companies could take place in the UK or in Scandinavia, but in either event would raise ethical and legal questions since a Council of Europe resolution,[3] accepted by the UK forbids the offering of substances (human material or extracts of such material) for profit. Finally if the glands were to pass out of our hands there could be difficulty in ensuring the return of *all* extracts from them. All the GH that can be extracted from UK pituitaries is needed for therapeutic purposes in the UK and other extracts from the glands have important research and commercial potential.

Recently it has been alleged that: 'hGH (UK) currently in use or an impurity in it accelerates osseous maturation either via thyroid or gonadal stimulation to a greater degree than it increases linear growth with the result that ultimate short stature (in most cases <3rd centile) is likely to result from the treatment of patients with short stature with hGH (UK)'.[4] This communication was delivered to the annual meeting of the BPA in York on 28 March 1979. The next day an article appeared in the *Glasgow Herald* headed 'HGH "Wonder cure" has turned sour for our poor growth youngsters'.[5]

The communication and the associated publicity were completely contrary to the published experience of the trial,[6] but in view of the distress caused to patients, their parents, and to the parents of potential patients, a new and detailed review of all patients treated with GH (UK) for whom bone age and height records are available was carried out.[7] Of 215 patients, 122 had isolated growth hormone deficiency, 63 had a deficiency of one or more pituitary hormones (panhypopituitarism), and 30 had a craniopharyngioma. Patients with craniopharyngioma or panhypopituitarism were treated with other hormones that could accelerate osseous maturation in addition to growth hormone. The duration of treatment varied from one to 13 years but since there was no relation between the time on treatment and rate of bone maturation it was possible to consider all cases together. The overall mean bone age velocity of patients with isolated growth hormone deficiency and panhypopituitarism was 1·00 and 0·97 bone age years respectively, but that of patients with craniopharyngioma was less: 0·57. These results show that treatment with GH (UK) does not cause pathologically accelerated bone maturation. To compare the growth in height with bone development it was necessary to calculate the height standard deviation score for bone age.[6] If osseous maturation is stimulated by GH (UK) to a greater degree than linear growth as alleged[4] then the height SD for bone age will become lower (that is more negative) as a result of treatment. In fact the opposite was observed in patients with craniopharyngioma and isolated growth hormone deficiency. In both groups the height SDs for bone age became significantly higher as a result of GH (UK) treatment showing that therapy increased growth in bone length more than osseous maturation. In the patients with panhypopituitarism no significant change in height SDs for bone age was observed, indicating that growth in height and osseous maturation was occurring proportionately.

Growth hormone treatment is one of the outstanding therapeutic successes in recent years and all paediatricians will wish to make it available to the greatest extent that supply will allow. The nationally co-ordinated scheme that operates in the UK ensures that this objective is fulfilled for our patients.

Congenital fibre type disproportion myopathy

A histological diagnosis with an uncertain clinical outlook

N. P. C. CAVANAGH, B. D. LAKE, AND P. MCMENIMAN

Departments of Neurology, Histopathology, and Orthopaedics, The Hospital for Sick Children, and The Institute of Child Health, London

SUMMARY Nine children with congenital fibre type disproportion (CFTD) are described. Their muscle biopsies contained type 1 fibres which were smaller than the largest type 2 fibres by at least 13·5%. Attention is drawn to the variable natural history of this disorder which generally carries a good prognosis but may sometimes be associated with fatal respiratory problems. For important therapeutic, genetic, and prognostic reasons CFTD must be distinguished from other conditions with similar histochemical or clinical features.

In 1969, Brooke and Engel reported the histographic analysis of muscle fibre types from 180 children and distinguished five separate groups of biopsies. One of these was characterised by relatively small, and sometimes excessively numerous, type 1 fibres and large type 2 fibres. Clinically the children in this group had been floppy infants whose condition generally improved as they grew older. Brooke (1973) subsequently described a further 12 cases to which he gave the name congenital fibre type dysproportion (CFTD). In the interim period other cases were recorded (Caille *et al.*, 1971; Noronha, 1973), although probably the earliest descriptions of this disorder were by Farkas-Bargeton *et al.* (1968) and Dubowitz (1969).

Since 1973 there have been a few similar reports (Fardeau *et al.*, 1975; Lenard and Goebel, 1975; Serratrice *et al.*, 1975), and Spiro *et al.* (1977) described 3 infants who died of respiratory failure all of whom had small type 1 muscle fibres.

We present a further 9 patients whose muscle biopsies showed the presence of type 1 fibres which were smaller than the largest type 2 fibres by more than 13·5%. We think that these children could be said to have CFTD and that this has important genetic and therapeutic implications which are of interest to paediatricians. We also wish to stress the difficulties of making this diagnosis and the need for further debate to delineate more fully the natural history and histochemical features of the disorder. The case histories of 2 children are given in full in order to give the range of clinical symptoms; the histories of all the children are summarised in Table 1.

Case histories

Case 1. Pregnancy was normal and there were normal intrauterine movements. The baby, a girl, was born at term by breech delivery with forceps to the aftercoming head, and weighed 2·8 kg. In the newborn period she was noted to be floppy and to have a left 'clicking' hip. There were no respiratory or feeding difficulties.

In the family history her mother had been a 'bottom shuffler'.

The child was first seen at this hospital aged 6 weeks, by which time she was smiling. On examination she was visually alert. She had a circumflex-shaped mouth but no obvious facial weakness. There was no tongue fibrillation and no fasciculatory finger movements. She was markedly hypotonic and could just move her limbs against gravity. She was areflexic. She was nursed in double nappies because of her hip.

Investigations at that time showed a CPK high on one occasion and normal on others. Electromyography of her right tibialis anterior muscle was myopathic. A muscle biopsy of her left quadriceps showed type 1 fibres which were smaller than type 2 ones (Table 1), and a small proportion (4½%) of fibres which might be considered as type 2C.

Table 1 *Summary of some of the clinical features of 9 cases of congenital fibre type disproportion*

Case	*Sex*	*Family history*	*Delivery*	*Presenting symptoms*	*Milestones*	*Operative procedures*	*Age when last seen (years)*	*Centile*		*Other comments*
								Height	*Weight*	
1	F	Mother had weak legs in childhood: now normal	Breech: forceps to the after coming head	Hypotonia. CDH	M: Delayed Sp: Slight delay S: Normal	R. femoral osteotomy	2¼	10th	10th	See full history
2	F	Parents were 2nd cousins. Two maternal cousins 'doubled jointed'	Forceps because of toxaemia	Hypotonia. Weakness	M: Delayed Sp: Normal S: Normal	L. adduction rotation osteotomy	2¼	10th	<3rd	Contractures at 2 months. Hypermobile hand joints. Improved with age
3	M	None	Caesarean section for previous placenta previa	Weakness. CDH. Vertical R. talipes	M: Delayed Sp: Normal S: Normal	Bilateral open reduction of hips and femoral osteotomies	2	3rd	<3rd	Contractures. Hypermobile joints of hands and feet. High arched palate. Mild scoliosis
4	M	None	Normal 1st of twins	Hypotonia. Joint hyperextensibility. Weakness	M: Delayed Sp: Normal S: Normal	None	1½	50th	<3rd	Contractures. Small penis and absent testes. Normal twin sister
5	F	None	Normal	Fixed dorsiflexed position of feet. Poor sucking	M: Delayed Sp: Delayed S: Delayed	Elongation of extensor tendons	2¾	<3rd	<3rd	Improving with age
6	F	None	Elective caesarean section	Delayed motor milstones	M: Delayed Sp: Normal S: Normal	Release of R. tendo achillis	6	<3rd	<3rd	Increased weakness exacerbated by operative immobilisation. Scoliosis. High arched palate
7	F	Two paternal cousins had CDH	Breech	Hypotonia. Bilateral talipes. CDH	M: Delayed Sp: Normal S: Normal	Derotation osteotomy. L. innominate osteotomy. Posterior medial release of both feet. Bilateral extension tendo achillis	3½	10th	10th	Improving with age
8	M	None	Breech	Dyspnoea	M: Delayed Sp } Not reliably S } assessed	Tracheostomy	Died aged 1¼	15th	15th	See full history
9	F	None	Normal	Stridor. CDH	M: Delayed Sp: Normal S: Normal	Open reduction L. hip	3¼	<3rd	<3rd	Frequent chest infections, stridor improving with age

M = Motor, Sp = speech, S = social, CDH = congenital dislocation of hip.

At follow-up there was concern about the instability of her right hip which tended to sublux and at age 2 years a right varus derotation osteotomy was performed.

Although she could sit at 7 months she was still not walking alone at 2¼ years when last seen. She was reluctant to bear weight, could not pull to stand, and could take only 2 steps holding. She shuffled on her bottom. Her social responses were appropriate for her age and she had good comprehension, but her speech was confined to single words. Her height and weight were on the 10th centile.

Case 8. Pregnancy and intrauterine movements were normal. Delivery was by breech at 36 weeks and Apgar score at one minute was 8. Birthweight was 3·7 kg. There were no problems in the newborn period and the baby, a boy, sucked well. He smiled at 6 weeks.

There were no worries about him until age 4 months when during a period of 2 days he became ill with a cough and fever. On admission to hospital he was found to be dyspnoeic and to have a collapsed left lung. Within a few hours his condition deteriorated and he required high concentrations of oxygen to maintain his blood oxygen (Po_2) levels. 4 ml of pleural fluid was aspirated which later grew a coagulase-positive staphylococcus.

On transfer to this hospital 4 days later he was noted to be hypotonic with normal reflexes. Closer questioning of the parents disclosed that head raising in the prone and supine positions had always been poor. There were no cranial nerve abnormalties. There were no dysmorphic features and no skeletal abnormalities. Bronchoscopy did not show any significant abnormality. A barium swallow showed incoordinate swallowing with reflux into the posterior nasopharynx; the lowest portion of the oesophagus was dilated, and normal oesophageal stripping waves were ineffective. Pulmonary arteriography and left ventricular angiography were normal.

Six days after admission, assisted ventilation became necessary because of persistent respiratory failure secondary to left-sided collapse, and subsequently he developed a right upper lobe pneumonia and a right tension pneumothorax. 10 days after admission his liver function was first assessed and his liver enzymes were found to be raised (alanine amino transferase 150 IU/1 and aspartate amino transferase 104 IU/1). His liver edge felt firm but there was no hepatomegaly. These enzyme abnormalities gradually improved during the next months.

Three weeks after admission his CPK was estimated and found to be raised (14·6 µmol/ml per hour at 37°C, normal <3·6). In view of a recent history of intramuscular injections, the significance of this finding was uncertain. However, subsequent estimations showed a persistent abnormality and, in view of this, electromyography and muscle biopsy were performed. Sampling with a concentric needle electrode in right deltoid and vastus medialis did not show any abnormality, but his biopsy from left tibialis anterior when he was 6 months showed the presence of type 1 fibres which were smaller than the type 2 with no other abnormality (Table 2). Three months after admission, a tracheostomy was performed and he continued to require assisted ventilation until the time of his death at 14 months. Repeat contrast investigations of the upper alimentary tract confirmed that reflux into the respiratory tract continued, so that it was difficult to be certain to what degree his respiratory difficulties were a reflection of this or of his myopathy. He continued to remain very hypotonic and weak and be unable to sit alone. Two weeks before he died he developed fits which were generalised and left focal. Epilepsia partialis continua down the left side was resistant to anticonvulsant treatment. His clinical condition after the onset of these fits deteriorated rapidly and computerised axial tomography (CAT) of his brain showed pronounced cerebral, cerebellar, and brain stem atrophy. He died from bronchopneumonia and congestive cardiac failure.

Table 2 *Summary of muscle biopsy features*

Case	*Age at biopsy (months)*	*Muscle biopsied*	*Fibre types percentage*				*Fibre size (µm)*			*Percentage difference by which type 1 is smaller*	
			1	*2A*	*2B*	*2C*	*1*	*2A*	*2B*	*Than 2A*	*Than 2B*
1	2	Vastus lateralis	37·5	29	13·5	4·5	14·25±2·2	16·5±2·2	16±2·2	13·6	10·9
2	14	Vastus lateralis	51	29	20		13 ±0·15	18·5±4	19·5±4	29·7	33
3	10	Vastus lateralis	33	24	43		14·5	16·5	17·5	12·1	17·1
4	12	Vastus lateralis	44	34	22		11 ±1·7	16·5±1·7	22 ±2	33·3	50
5	18	Tibialis anterior	51·1	33	15·5		18 ±2·4	21 ±2·9	26 ±2·2	14·2	30·7
	18	Gastrocnemius	50·5	37	12·5		13·5±1·4	17 ±2·2	21·5±4·4	20·6	37·2
6	30	Vastus lateralis	50	27	23		18·6±3·6	28·7±4·8	29·4±5·4	35	36·6
7	30	Peroneus	55	31·5	13·5		28·5±6·7	40 ±4·9	43 ±4·9	28·7	33·7
8	6	Tibialis anterior	37·5	42	20·5		13·5±4	27 ±4	24·5±4	50	44·9
9	27	Vastus lateralis	52		48		7–10 µm	16–26 µm			

Normal fibre diameters are from about 14 µm at birth to about 21 µm at 2½ years.

Investigations found to be normal were: sweat test, blood viral antibody screen, absence of vacuolated lymphocytes, urine mucopolysaccharides, blood copper, and zinc. Urine amino- and organic acids on some occasions were normal and at other times showed a raised glycine and taurine and raised parahydroxyphenyllactic and parahydroxyphenylacetic acid. These abnormalities were considered to be a reflection of his impaired liver function. He was shown to have a low IgG (26 IU/ml) and a high IgM (>170 IU /ml) at 4 months. His height and weight were both on the 15th centile.

Investigations

Electromyography was performed in all but one patient. The findings suggested a myopathy in Cases 1, 3, 4, and 5, were normal in Cases 2, 8, and 9, and suggested denervation but with normal nerve conduction studies in Case 6. CPK estimations were slightly raised in Cases 4, 5, and 6, significantly raised in one (Case 8), slightly raised on one occasion and normal on another in Case 2, and normal in the others.

One (Case 5) was extensively investigated on account of her low height and weight. The following investigations were normal: sweat test, barium meal and follow through, barium enema, jejunal biopsy, duodenal enzymes on aspiration. No organism was found in the pancreatic juice although she had been treated several months previously with metronidazole for giardia infection of the gut. Her serum albumin was normal.

Other investigations which were performed and found to be normal are shown in Table 3.

A muscle biopsy was obtained in all cases and treated as described previously (Lake and Wilson, 1975). In addition, muscle tissue was obtained from some patients during the course of orthopaedic surgery. The least diameter of a minimum of 50 fibres of each type covering several muscle fascicles was measured in the acid preincubated 'ATPase' preparations using a calibrated eyepiece graticule. Most muscle fibres do not show a uniform shape and, for this reason, the minimum diameter was measured as this gives the best approximation to the true diameter regardless of the plane of section. An indication of the diameters measured is shown in Fig. 1. The mean diameter and SD for each type is shown in Table 2. The fibre type percentage is calculated from a fibre type analysis of several muscle fascicles containing at least 200 muscle fibres, using the acid preincubated 'ATPase' preparations to define the three main fibre types.

Table 3 *Investigations for which the results were normal*

Investigation	*No. of patients investigated*
Blood thyroxine	5
Thyroid stimulating hormone	1
Pyruvate and lactate	4
Urine amino- and organic acids	5*
Blood amino-acids	6
Urine mucopolysaccharides	2
Liver function tests	2†
Blood chromosome analysis	2
CAT of the skull	2
Congenital infection screen	3

*The urine of Case 8 intermittently contained raised glycine and taurine.
†Serum alanine and aspartate aminotransferase levels were raised in Case 8.

Muscle tissue was obtained at necropsy from Case 8 and frozen for cryostat sectioning. Samples were taken from left and right tibialis anterior, vastus lateralis, psoas, diaphragm, rectus abdominis, sternomastoid, biceps brachialis, sartorius, and trapezius.

Pathology

The only change noted in each of the (*in vivo*) biopsies was a disproportion in size of type 1 and type 2 fibres. There was no increase in numbers of central nuclei, endomysial connective tissue, degeneration, or other nonspecific features associated with denervating or myopathic conditions. The more specific features of nemaline myopathy or central core disease were not seen. In one biopsy (Case 7) many of the type 1 fibres showed 'motheaten' characteristics.

The disproportion of the size of type 1 and the largest type 2 fibres (Table 2) was always greater than 13·5% and in 7 out of 9 patients the 2B fibres were larger than the 2A ones. The proportion and size of type 1 fibres were in most cases within the normal range. The coefficient of variability of the type 2 fibres was less than 250 in all patients.

In Cases 2 and 9 a biopsy of sartorius taken during reduction of the dislocated hips did not show disproportion of fibre diameters, although biopsies of vastus lateralis taken earlier (Case 9), or later (Case 2), showed the characteristic disproportion.

The muscles sampled at necropsy of Case 8 showed pronounced intersample differences and had changed remarkably since the biopsy taken at age 6 months. In each muscle examined from this patient there was an increase in endomysial connective tissue, a greater number of central nuclei, and pronounced variation in fibre diameters which did not correlate with fibre type. Cytoplasmic bodies, staining bright red in the trichrome preparations, were present even in the more mildly affected muscles. Considerable infiltration by histiocytes showing acid phosphatase activity was noted with only little evidence of regenerative changes although some of the central nuclei were plump and occasionally several were present in one fibre. The degree of involvement could be roughly graded from the least affected muscle to the most affected in the following order: tibialis anterior, sternomastoid, sartorius, biceps brachialis, psoas, rectus abdominis, vastus lateralis, trapezius, and diaphragm. In Figs 1–4 the biopsy findings are compared with those found at necropsy.

The lungs showed bronchopneumonic changes and some hyaline membrane formation. Other tissues appeared normal or showed only slight changes. In particular there was no evidence of any abnormality of anterior horn cells, nor was there evidence of storage disease.

Discussion

Some of the clinical features of our 9 cases are shown in Table 1. A family history of neuromuscular problems was present in only 2 children (Cases 2 and 7); in one the parents were second cousins and two maternal cousins were said to be 'double jointed', and in the other case two paternal cousins had had CDH but no other neuromuscular problems. Six of the 9 patients were girls.

Pregnancy was normal in all but one instance in which there was terminal toxaemia, and intrauterine movements were experienced normally by all mothers.

Delivery was complicated in 6 out of 9 patients: Cases 1, 7, and 8 were breech presentations, Cases 3 and 6 were caesarean sections, one electively and the other for placenta praevia, and foreceps was used in Case 2.

Generalised hypotonia and weakness were noted early in 6 children and became evident within the subsequent 2 years in the remaining 3 (Cases 5, 6, 9) although in Cases 5 and 9 these symptoms were only slight. There was no significant deterioration in any patient after age 2 years and in 3 there was greater improvement in strength than might have been anticipated from natural maturation alone.

Respiratory difficulties were present in the newborn period in only one child (Case 9) who had laryngeal stridor. One other patient (Case 5) sucked poorly.

Congenital dislocation of the hip was noted in about one-third of our cases. Other skeletal abnormalities were not uncommon and included deformities of the feet in 3 children (Cases 3, 5, and 7), scoliosis and high arched palate in Cases 3 and 6. Cases 2, 4, and 8 had no skeletal deformities. Muscle contractures commonly developed and reflexes were depressed or absent. Height and weight tended to be about or below the 3rd centile in most instances. Motor milestones were delayed in all patients, but speech and social development was normal in all except Cases 1 and 5.

These clinical features are very like those described by Brooke and Engel (1969) and Brooke (1973) in the majority of their patients. In their series there was a slight preponderance of females, and in ours there were twice as many females as males, but the numbers are too small to form any valid conclusions. Delivery was complicated in 6 out of our 9 cases whereas it was normal in all but 2 of Brooke and Engel's cases. Half their patients had high arched palates whereas this was a feature in only 2 of ours. Brooke commented that recurrent respiratory infections 'may be a problem'. This was true of Case 9 in our series, and in Case 8 the clinical picture was dominated from age 4 months onwards by persisting and very severe respiratory difficulties necessitating continued assisted ventilation. This child is reminiscent of those described by Spiro *et al.* (1977) and leads us to confirm their impression that respiratory failure is a rare but definite feature in CFTD.

Although the clinical features of CFTD are distinctive they are by no means exclusively diagnostic and may also be present in several other congenital myopathies—such as nemaline myopathy and infantile myotonic dystrophy. A disproportion in fibre sizes, type 1 fibres being smaller than type 2, may also be present in these two conditions with the result that it may be difficult to distinguish them one from another and from CFTD. This difficulty is illustrated by the report of Caille *et al.* (1971) where it is clear that their Case 1 had CFTD and their Case 2 nemaline myopathy.

None of the biopsies of our patients contained nemaline rods whereas they were present in 2 of the cases of Brooke and Engel (1969), and it is interesting that these 2 patients had very high arched palates—a feature characteristic of nemaline myopathy. We feel that these patients could more properly be said to have had nemaline myopathy. Although we recognise that nemaline bodies may be found in a variety of conditions (Dubowitz and Brooke, 1973) and that therefore the presence of such bodies does not necessarily imply the diagnosis of nemaline myopathy, nevertheless it would appear to us more logical to call the association of nemaline bodies and type 1 fibre atrophy, nemaline myopathy, than to attempt to extend the histochemical picture of CFTD to include the presence of nemaline bodies.

The distinction between CFTD and neonatal myotonic dystrophy may be difficult on both histochemical and clinical grounds in the early stages. However in over 90% of cases of neonatal myotonic dystrophy, myotonia can be clinically

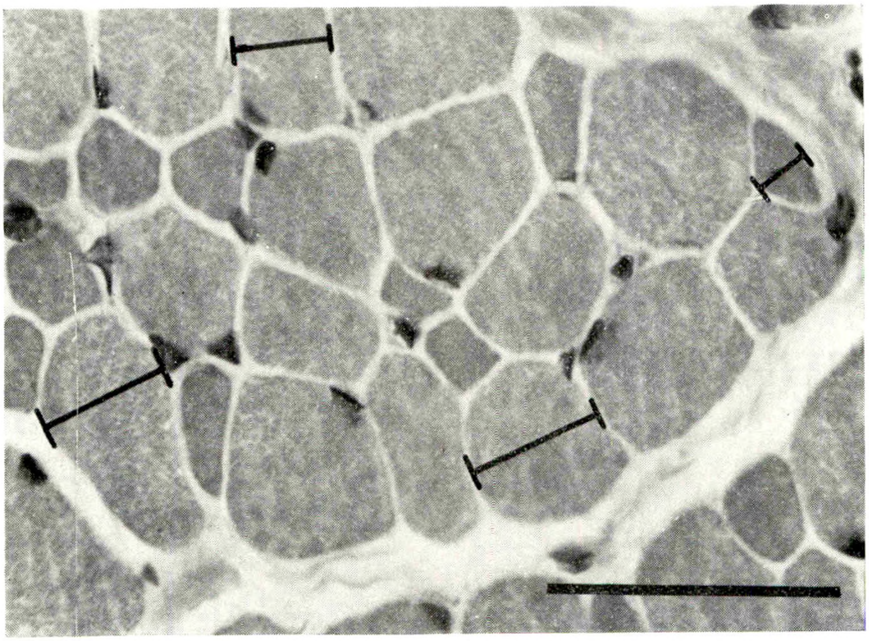

Fig. 1 *Biopsy of L. tibialis anterior at 6 months (Case 8). Haematoxylin and eosin preparation showing two populations of fibres without other myopathic features. An indication of the fibre diameters measured is also shown for four fibres. Scale mark 50 μm. × 700*

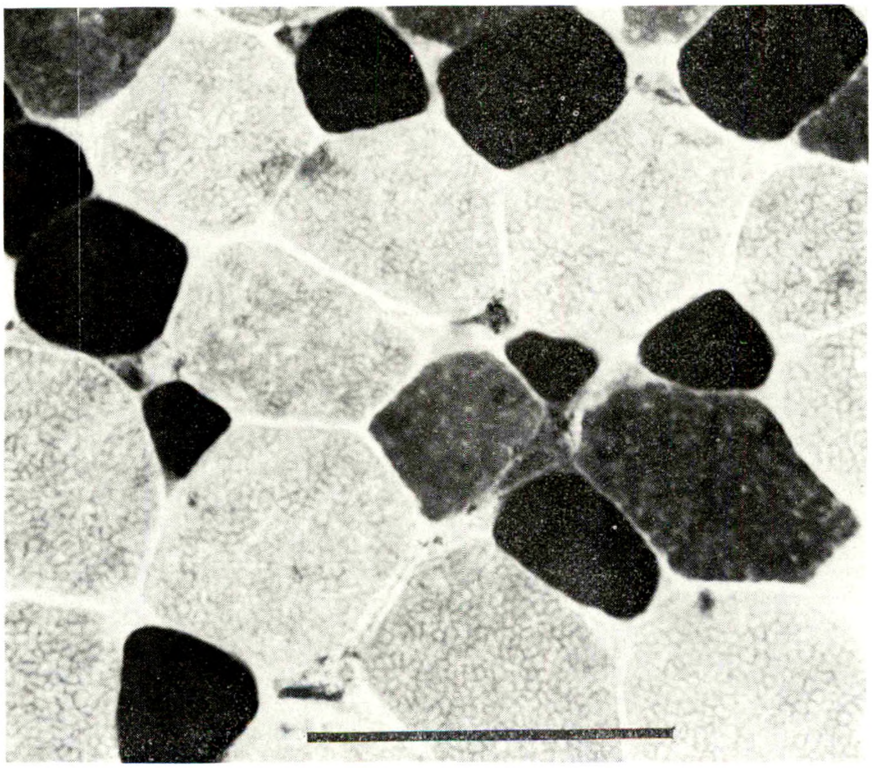

Fig. 2 *Biopsy L. tibialis anterior (Case 8). 'ATPase' preparation after preincubation at pH 4·3 showing that the small fibres are all of type 1. Scale mark 50 μm. × 950*

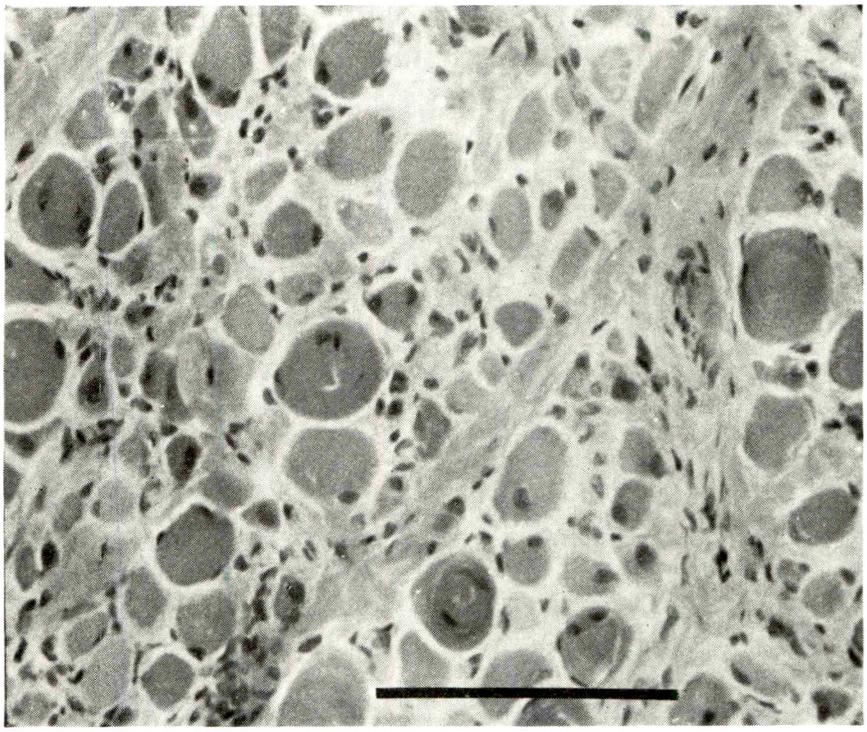

Fig. 3 *Necropsy diaphragm muscle (Case 8). Haematoxylin and eosin preparation showing pronounced variation in diameter of fibres, increase in connective tissue, central nuclei, and whorled fibres. Scale mark 200 μm. × 200.*

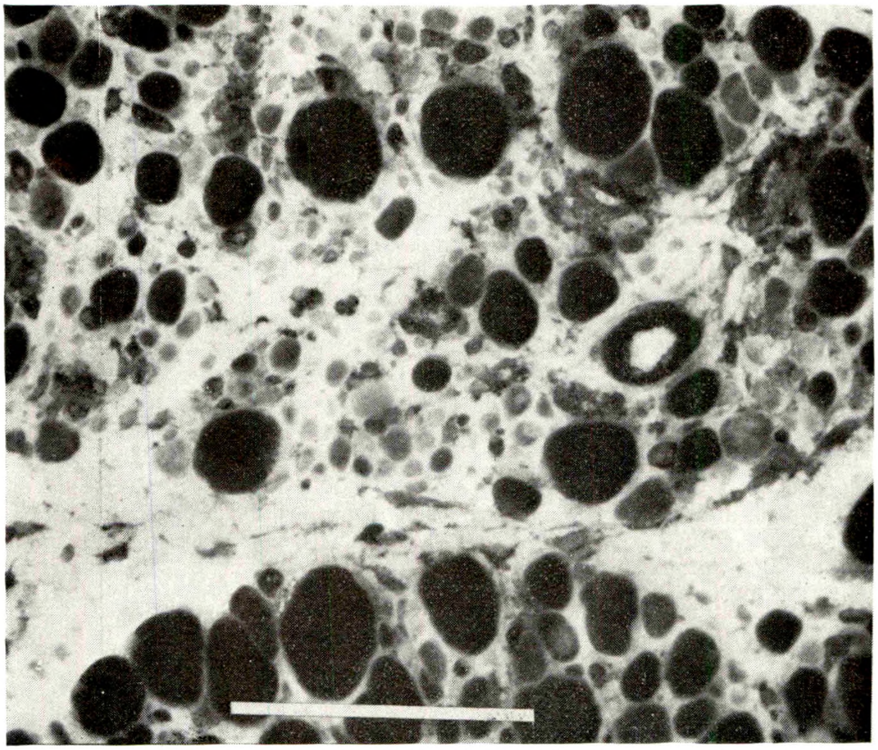

Fig. 4 *Necropsy trapezius muscle (Case 8). 'ATPase' preparation after preincubation at pH 4·3 showing that the orderly pattern of the biopsy (Fig. 2) has been replaced and that the large fibres are now mainly type 1. Scale mark 100 μm × 400*

elicited in the mother. None of the mothers of our cases had myotonia.

The significance of the presence of 'motheaten' type 1 fibres in Case 7 is uncertain, but it is interesting that this patient was the only one in whom bilateral talipes equinovarus was present; this association was reported previously by Dubowitz and Sharrard (1968).

The absence of fibre type disproportion in sartorius muscle in 2 patients confirms the impression of Spiro *et al.* (1977) that there may be 'striking intersample differences', and this is also seen in the marked differences between the muscles sampled at necropsy of Case 8.

The appearances of the muscle at necropsy in Case 8 are very similar to those of congenital muscular dystrophy and it could be speculated that some cases of congenital muscular dystrophy may arise from a fibre type disproportion at birth. However Case 8 presented with respiratory failure at 4 months of age, and the absence of severe neuromuscular problems in the early months of life makes the clinical diagnosis of congenital muscular dystrophy unlikely.

The clinical differential diagnosis of CFTD includes a number of other conditions. The picture initially may suggest a severe form of spinal muscular atrophy. In view of the very different prognosis in these two conditions it is clearly important to distinguish them, even to the extent of performing a muscle biopsy.

The combination of foot deformities, congenital dislocation of the hip, and flexion contractures often leads to a diagnosis of arthrogryposis multiplex congenita. This condition is a clinical definition of what is probably a heterogeneous group of disorders (Wynne-Davies and Lloyd-Roberts, 1976), some of which are myelopathic in origin presenting as 'wooden dolls' (Brandt, 1947), and others myopathic with weakness, hypotonia, and flexion contractures (Adams, 1975). Muscle biopsy may be the only way of distinguishing CFTD from this latter group.

Although none of our patients had contractures at birth, several soon developed them. These contractures present a different clinical problem from the rigid contractures of arthrogryposis multiplex congenita, and we feel the combination of weakness, hypotonia, and posture are significant aetiological factors.

Only one child (Case 7) had bilateral congenital talipes equinovarus at birth, which contrasts with its more usual incidence in arthrogryposis multiplex congenita (Lloyd-Roberts and Lettin, 1970). Calcaneo-valgus deformity of the feet was seen in 3 patients, requiring elongation of the extensor tendons and dorsal capsulotomy of the ankle joint in one.

Finally in the clinical differential diagnosis, is the syndrome of multiple congenital dislocations associated with characteristic facial abnormality (Larsen *et al.*, 1950). This diagnosis was initially given to 2 of our patients before muscle biopsy and it is important to distinguish this condition from CFTD as the management of the congenital dislocated hip is different. In Larsen's syndrome reduction of the dislocated hips has proved to be unrewarding (G. Lloyd-Roberts, personal communication), whereas in CFTD it is worth while.

Approximately one-third of our cases had dislocated hips and this is similar to the incidence reported by Brooke (1973). In his series good results were obtained with conservative treatment. This has not been our experience. All hips which were dislocated have required open reduction.

One of our patients was immobilised for a prolonged period after fracturing her tibia and a consecutive operation on her tendo achillis. She became noticeably weaker after this. Briefer periods of immobilisation for operative procedure in the other patients has not been followed by any physical deterioration.

Extensive investigations of the gastrointestinal tract in one pateint did not show any abnormality. As yet there is no explanation for the observation that many children with CFTD have heights and weights below the 3rd centile.

The question of inheritance of CFTD is an interesting one. None of our cases had an affected parent or sibling, but Case 6 of the series of Brooke and Engel (1969) had an elder brother with similar clinical features, and the father of these 2 boys was also said to have been weak as a child but to have outgrown the condition. Neither the brother nor the father of the index patient was biopsied and we feel from the information presented that the father did not have the same condition as his 2 sons. Fardeau *et al.* (1975) also reported a father and 2 siblings. However the father had at no time had any muscle weakness and his biopsy contained nemaline bodies and these features lead is to suspect that he too did not have the same condition as his children. Kinoshita *et al.* (1975) reported a boy and his mother who both had type 1 fibre atrophy and also nemaline bodies present on muscle biopsy. Although the authors felt that these patients had CFTD, we think their condition should be more properly called nemaline myopathy. It seems likely therefore that CFTD is inherited as a recessive trait.

From our experience of these 9 cases we agree with the general opinion that CFTD is a histological diagnosis which is usually associated with a clinical presentation having a favourable prognosis. However the progressively deteriorating clinical and histochemical features of our Case 8 lead us to agree with

Spiro *et al.* (1977) that a benign outlook is not invariable.

We thank Dr D. G. F. Harriman for allowing us to review the sections of the first biopsy from Case 9, and Drs E. M. Brett, R. Dinwiddie, D. N. Grant, J. Wilson, and Mr G. C. Lloyd-Roberts for permission to study their patients.

We are grateful to Dr R. G. Willison for help with electromyography. Mrs V. Smith, FIMLT, provided skilled technical assistance.

Echocardiographic findings of large patent ductus arteriosus in the very low birthweight infant before and after treatment with indomethacin

H. L. HALLIDAY, T. HIRATA, AND J. P. BRADY

Children's Hospital of San Francisco, and Cardiovascular Research Institute, University of California, USA

SUMMARY 17 very low birthweight infants (mean birthweight 850 g) with large patent ductus arteriosus (PDA) were studied by echocardiography before and after treatment with indomethacin. Before treatment left heart dimensions were increased suggesting large left-to-right shunt. Echographic measurements of augmented left ventricular (LV) contraction could be attributed to increase in preload, and reduction in afterload in PDA. After indomethacin, in infants showing clinical response, left heart dimensions returned rapidly to normal and LV contraction became normal or reduced. Two infants had reduced LV contraction with persistent pulmonary oedema suggesting LV failure. In contrast, infants showing no clinical response to the drug also had no significant changes in echographic measurements. Right ventricular systolic time intervals (RPEP/RVET) did not alter after indomethacin treatment in either group, suggesting that the drug does not increase pulmonary vascular resistance.

Echocardiographic assessment of left-to-right ductus shunt by measuring the left heart dimensions has been a major advance in the management of infants with patent ductus arteriosus (PDA). From left atrial to aorta ratio (LA/Ao) (Silverman *et al.*, 1974), left atrial dimension (LAD), and left ventricular end-diastolic dimension (LVEDD) (Baylen *et al.*, 1975) the size of shunt can be estimated. The echocardiogram can also be used to assess left ventricular performance (Sahn *et al.*, 1974) and pulmonary vascular resistance in the newborn (Hirschfeld *et al.*, 1975a; Riggs *et al.*, 1977). Measurements of left ventricular function in infants with PDA before and after ductus ligation have already been reported (Baylen *et al.*, 1977), but no data are available on the effects of indomethacin on left ventricular function and pulmonary vascular resistance in infants with large PDA. The purpose of this paper is to present our echocardiographic findings in 17 very low birthweight infants with large PDA who were given indomethacin.

Patients and methods

17 infants of mean gestational age 27·2 weeks and mean birthweight 850 g were given indomethacin in a total dose of 0·2 to 0·6 mg/kg for large PDA. The diagnosis of PDA and the method of administration of the drug have been described elsewhere (Halliday *et al.*, 1979). The mean total dose of indomethacin was 0·38 mg/kg and the median age at treatment was 6 days (range 4–66). Four infants had severe respiratory distress (requiring $F_{IO_2} > 0 \cdot 60$ and assisted ventilation after 24 hours of age). 15 infants were treated with mechanical ventilation, one with mask CPAP, and one did not require ventilatory support when the drug was given. Six infants had been treated with digoxin and 5 with frusemide before being given indomethacin. There were 13 girls and 4 boys.

Echocardiograms were recorded using an Ekoline 20 ultrasonoscope (Smith-Kline Instruments) with a 5 MHz focused transducer. Studies were performed serially before giving indomethacin and within 3 days afterwards (mean 1·3). LAD and LVEDD were measured using methods previously described (Feigenbaum, 1972). LA/Ao was measured using the method of Silverman *et al.* (1974) (coefficient of variation ± 7·0%). Percentage shortening of the internal diameter (SID) of the left ventricle was calculated from the formula (Baylen *et al.*, 1977):

$$\%\,SID = (LVEDD - LVESD)/LVEDD \times 100$$

where LVESD = left ventricular end systolic dimension (Fig. 1). The systolic time intervals of both ventricles, the pre-ejection period (PEP), and ventricular ejection time (VET) were measured as previously described (Hirschfeld *et al.*, 1975b; Halliday *et al.*, 1977) (Fig. 2). Many of these tiny infants were being mechanically ventilated at the time of study and this may alter these measurements. For this reason at least 10 consecutive ventricular systoles were examined to give the mean systolic time intervals (coefficient of variation ± 4·8%).

Values before and after indomethacin were compared by the paired Student's *t* test.

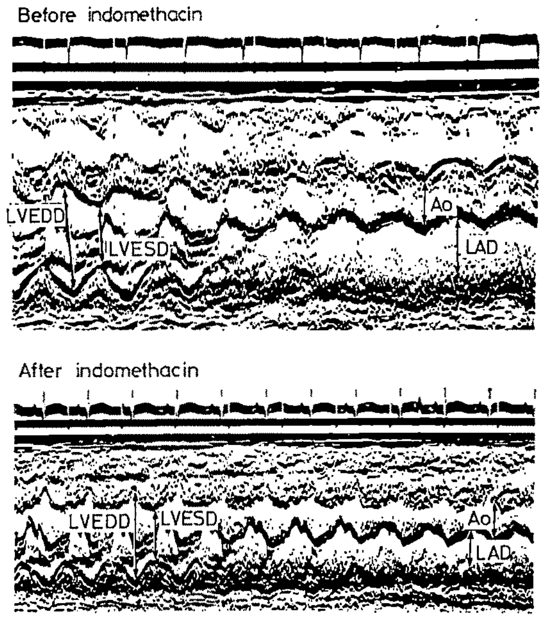

Fig. 1 *Echocardiograms of left ventricle with sweep to aorta and left atrium before and after indomethacin treatment for large PDA in a 750-g infant. The echocardiograms are not recorded on the same scale. Fig. 1a (before indomethacin) shows left ventricular end-distolic dimension (LVEDD) = 1·7 cm, left ventricular end-systolic dimension (LVESD) = 0·9 cm, percentage shortening of internal dimension of LV (% SID) = 47%, left atrial dimension (LAD) = 0·9 cm, and left atrial to aorta ratio (LA/Ao) = 1·6:1. After indomethacin (Fig. 1b) the measurements become LVEDD = 1·35 cm, LVESD = 0·8 cm, % SID = 41%, LAD = 0·7 cm, and LA/Ao = 1·2:1.*

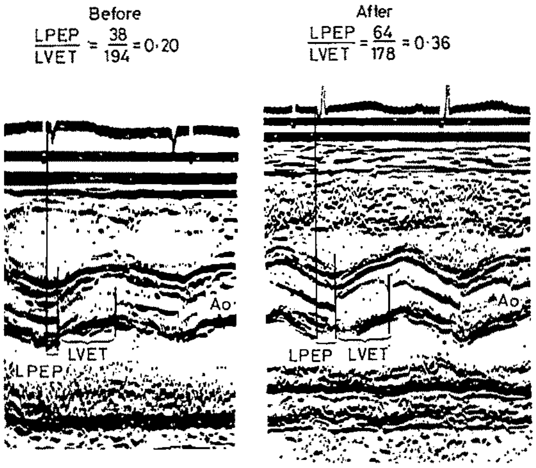

Fig. 2 *Echocardiograms of aortic valve at paper speeds of 100 mm/s before and after treatment with indomethacin in a 750-g infant. Before treatment left ventricular pre-ejection period (LPEP) = 38 ms, left ventricular ejection time (LVET) = 194 ms, and LPEP/LVET = 0·20. After treatment LPEP = 64 ms, LVET = 178 ms, and LPEP/LVET = 0·36.*

Results

After treatment with indomethacin, 13 of 17 infants showed good clinical response with reduced intensity of the murmur, decreased pulses and praecordial activity, and less need for ventilatory support (group 1). Within 3 days the PDA had closed in these infants. The remaining 4 infants showed little or no clinical response to indomethacin (group 2). These two groups of infants were of similar gestational ages, birthweights, sexes, and age at treatment. Incidence of severe respiratory distress, and pretreatment with digoxin or frusemide was also similar (Table 1).

Echocardiographic findings before treatment were similar in both groups (Table 2).

HR = Heart rate; LAD = left atrial dimension; LA/Ao = left atrial to aorta ratio; LVEDD = left ventricular end diastolic dimension; % SID = percentage shortening of the internal dimension of LV; LPEP = left ventricular pre-ejection period; LVET = LV ejection time; RPEP = right ventricular pre-ejection period; RVET = RV ejection time; SBP = systolic blood pressure; DBP = diastolic blood pressure.

Left heart dimensions (LAD, LA/Ao, and LVEDD). These echographic measurements of left heart size were increased before treatment in both groups when compared with normal values of Baylen *et al.* (1975, 1977) and Silverman *et al.* (1974) (Figs 1 and 3). Our normal LA/Ao values are somewhat higher than those of Silverman *et al.* (1974) 1·1 ± 0·1 (H. L. Halliday and J. Keroes, 1977, unpublished observations). The measurements in responding infants (group 1) tended to be higher than those in nonresponding ones (group 2) (Table 2) but the differences were not statistically significant. After indomethacin treatment, group 1 infants showed decrease in left heart dimensions to the normal range (Fig. 1b), often within 24 hours and, in 2 infants, by 4 hours after administration. Fig. 4 shows measurements from a typical infant.

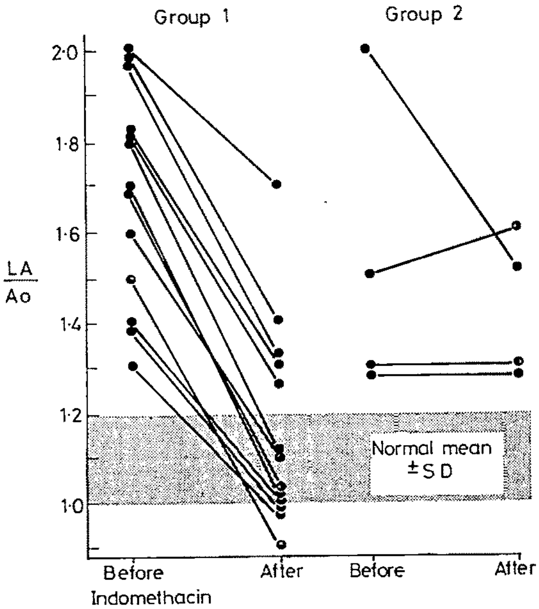

Fig. 3 *Comparison of changes in LA/Ao ratio after treatment with indomethacin in groups 1 and 2. Shaded area represents normal mean ± 1 SD (H. L. Halliday and J. Keroes, 1977, unpublished observations).*

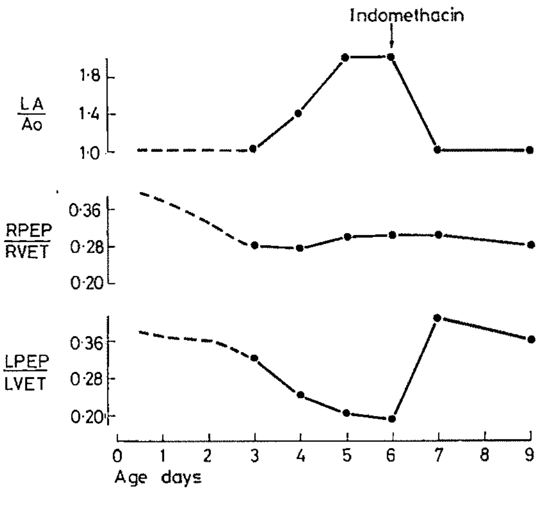

Fig. 4 *Measurement from serial echocardiograms of a 750-g infant who developed a large PDA. Dashed lines show previously reported results (Silverman et al., 1974; Halliday et al., 1978). As clinical evidence of PDA appears about the fourth day of life, LA/Ao ratio increases and LPEP/LVET ratio decreases while RPEP/RVET ratio is unchanged. Indomethacin was given on day 6 and LA/Ao and LPEP/LVET rapidly returned to normal while RPEP/RVET did not change.*

Percentage shortening of internal dimension of LV (% SID). Levels before treatment were about 40% (normal = 33·5%). After treatment group 1 infants had a decrease in % SID to 34·8% ($P<0·01$), but group 2 infants showed no such change (Table 2 and Fig. 5).

Systolic time intervals. In both groups mean LPEP/LVET was less than 0·26 (Figs 2 and 6) and normal for preterm infants without PDA is 0·32 (Halliday *et al.*, 1978). The ratio was decreased as a result of reduced LPEP and increased LVET (Table 2). After treatment values returned to normal in group 1 (Figs 2 and 6). Mean RPEP/RVET ratios were normal in both groups and were unaffected by indomethacin.

Blood pressure and heart rate (Table 2). Heart rate did not alter in either group but blood pressure in responding infants increased significantly from mean 51/24 to 62/30 mmHg.

Correlations. LPEP/LVET was negatively correlated with LA/Ao by the following formula: $\text{LPEP/LVET} = -0·14\,(\text{LA/Ao}) + 0·48$ ($r = -0·67$) and positively with diastolic blood pressure—$\text{LPEP/LVET} = 0·004\,(\text{DBP}) + 0·17$ ($r = 0·45$).

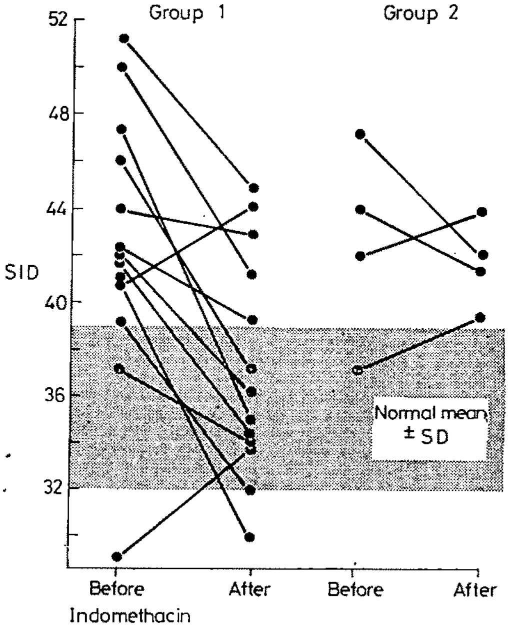

Fig. 5 *Comparison of % SID changes before and after treatment with indomethacin in groups 1 and 2. Shaded area represents normal mean ± 1 SD (Baylen et al., 1975, 1977).*

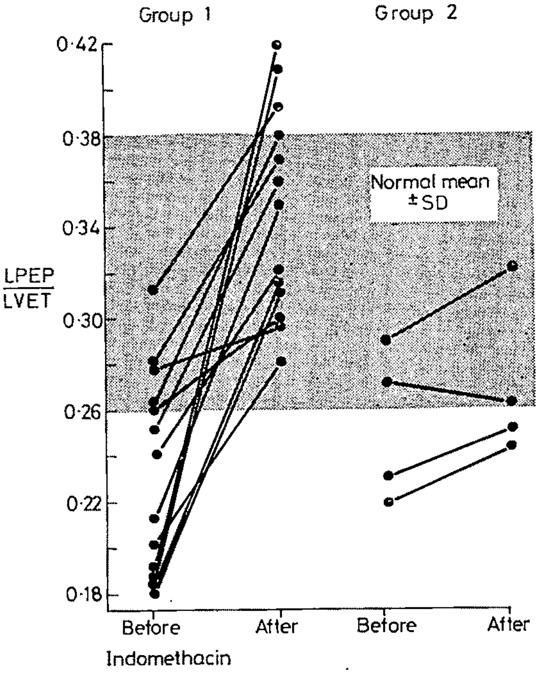

Fig. 6 *Comparison of changes in echocardiographic ratio LPEP/LVET in groups 1 and 2 after indomethacin treatment. Shaded area represents normal mean ± 1 SD (Halliday et al., 1978). Note the 2 infants in group 1 in whom LPEP/LVET was over 0·40 after treatment.*

Discussion

In the infant with large PDA, torrential left-to-right shunt will result in left ventricular and left atrial dilatation (Silverman *et al.*, 1974; Baylen *et al.*, 1975). Left atrial and left ventricular end-diastolic dimensions, and left atrial to aorta ratio have been shown to increase in left-to-right shunts including large PDA. After ductus ligation these dimensions rapidly revert to normal (Silverman *et al.*, 1974; Baylen *et al.*, 1975). There have been relatively few echocardiographic studies of left ventricular function in large PDA (Kaye *et al.*, 1975; Sahn *et al.*, 1976; Baylen *et al.*, 1977). Because of the reduced afterload, shortening of left ventricle (% SID) will increase and may spuriously suggest improved left ventricular contractility in PDA (Quinones *et al.*, 1975). Similarly, the ratio LPEP/LVET, which has been used as a measure of LV contractility (Weissler *et al.*, 1969; Halliday *et al.*, 1977), will be influenced by reduction in afterload in PDA.

Our infants with large PDA had increased left

COLLEGE OF MEDICINE LIBRARY

heart dimensions and presumably raised LV preload. In addition, increased % SID, and decreased LPEP/LVET could be reflections of the decreased afterload. After indomethacin administration left heart dimensions decreased rapidly and the changes were similar to those observed after ductus ligation. In indomethacin-treated infants whose murmurs remained, no significant reduction in left heart dimensions occurred. Although only 4 such infants were studied, 3 needed subsequent ductus ligation for continued failure. These infants probably attained similar blood levels as responding infants because they developed reduced urinary excretion of similar severity (Halliday *et al.*, 1979). Responding infants also demonstrated reduction in % SID, and increase in LPEP/LVET. We attribute these changes to increase in LV afterload and decrease in preload to normal levels after closure of the ductus. This is consistent with the relationship found between LPEP/LVET and diastolic blood pressure (afterload) and LA/Ao ratio (preload). It is possible however, that indomethacin had a direct myocardial depressive effect. The drug has been shown to raise coronary vascular resistance in the isolated animal heart without changing performance (Schror *et al.*, 1976), and a recent report of infant death from myocardial infarction and pneumonia after treatment with indomethacin has been published (Merritt *et al.*, 1978). Nevertheless, we feel that the signs of decreased LV contractility after indomethacin were due to the effect of ductus closure rather than to myocardial depression as they did not occur in infants whose ductus remained open. Furthermore the changes were similar to those after ductus ligation (Park *et al.*, 1973; Baylen *et al.*, 1975).

In 2 infants the echographic signs of decreased LV contractility were exaggerated with % SID below 32 and LPEP/LVET over 0·40 after treatment. These infants had persistent signs of pulmonary oedema, despite clinical closure of the ductus. This finding is in keeping with previous reports of depressed LV function after ductus ligation (Park *et al.*, 1973; Baylen *et al.*, 1975). We feel that LV failure resulted from rapid ductus closure with sudden increase in afterload to normal levels which stressed the already dilated and compromised LV.

Right ventricular systolic time intervals (RPEP/RVET) have been shown to correlate with pulmonary vascular resistance in infants and children (Hirschfeld *et al.*, 1975a). Despite a recent study showing increased pulmonary vascular resistance after administration of indomethacin to premature goats (Tyler *et al.*, 1975) we found no echocardiographic evidence to support this finding in our very low birthweight infants.

In summary, very low birthweight infants with large PDA have echocardiographic evidence of increased left heart dimensions and augmented LV contraction as a result of increased preload and reduced afterload. After ductus closure with indomethacin left heart dimensions rapidly return to normal (in 2 infants within 4 hours of treatment). There was no evidence of increased pulmonary vascular resistance after treatment but 2 infants showed signs of decreased LV contractility and had persistent pulmonary oedema possibly due to LV failure. This we attribute to the effects of rapid ductus closure with sudden increase in afterload rather than to direct myocardial depression by indomethacin.

We thank Dr A. M. Rudolph, Dr J. Keroes, and Dr H. C. Mulholland for help and advice in preparation of this manuscript, and Miss Denise McAfee for typing it.

This study was supported in part by Pulmonary Scor HL 19185 from the United States Public Health Service.

A prospective study of 18 infants of chronic HBsAg mothers

FLORINDO MOLLICA, SALVATORE MUSUMECI, SALVATORE RUGOLO, AND TERESA MATTINA

Department of Paediatrics, University of Catania, and Clinica Ostetrica e Ginecologica 2^, Santo Bambino Maternity Hospital, Catania, Italy

SUMMARY 28 of 1002 pregnant Sicilian women (2·8%) were asymptomatic HBsAg chronic carriers. 18 children of these women were followed and at least 15 of them showed evidence of transplacental infection with HBsAg, resulting either from the presence of the antigen in cord blood, or from the development of the corresponding antibody in the serum within the first 2 months of life. Despite this, only 2 or 3 of the infants developed chronic antigenaemia from age 2–4 months. Only the infants whose mothers were HBeAb-negative, and who themselves remained HBsAb-negative during the first months of life, became HBsAg carriers. On the basis of these results, a strategy is suggested for selecting infants from areas with a high prevalence of HBsAg carriers so that they can be given passive immunisation with hyperimmune globulin.

The application of new techniques for demonstrating hepatitis B surface antigen (HBsAg) to the study of maternofetal transmission of hepatitis B (so-called vertical transmission) has raised more questions than it has resolved. Unresolved problems include the prevalence of cord blood antigenaemia in children of chronic carrier mothers, the successive development, duration, and clinical implications of the antigenaemia in these children, and the possibility of its prevention.

In order to obtain information on these topics, we identified a group of pregnant women who were asymptomatic chronic HBsAg carriers, and followed their children for several months after birth, with clinical and laboratory examinations.

Our study indicated that HBsAg-positive mothers usually transmit the antigen to their babies, but also that only a few of these infants develop persistent antigenaemia with or without signs of hepatitis. On the basis of these findings we suggest a possible strategy for the prevention of persistent HBs antigenaemia in children of carrier mothers.

Materials and methods

1002 unselected pregnant women admitted to this maternity hospital, where over 6000 deliveries a year take place, were screened for HBsAg by the reverse haemagglutination method (Hepanosticon, Organon). All the positive sera were retested by radioimmunoassay (AUSRIA II, Abbott Laboratories) and confirmed to be positive, and determinations of bilirubin, aspartate transaminase (AST), and alanine transaminase (ALT) were made. A second radioimmunoassay for HBsAg was made after 3–6 months in order to confirm the chronic carrier state.

The HBsAg-positive women were also tested for HBcAb, by radioimmunoassay (CORAB, Abbott Laboratories), and for HBeAg and HBeAb by immunodiffusion techniques, using e antigen and antibody kindly supplied by Dr Linsen (Copenhagen).

The babies of the HBsAg-positive mothers were examined clinically at monthly intervals, and their sera tested for HBsAg (AUSRIA II, Abbott Laboratories), HBsAb (AUSAB, Abbott Laboratories), bilirubin, AST, and ALT. The babies were all formula fed. When available, their fathers were also studied.

Results

28 of the 1002 women (2·8%) were asymptomatic

chronic carriers of HBsAg. None had a history of clinical hepatitis, jaundice, or liver enlargement; serum transaminases and bilirubin levels were normal. The 28 women were informed of their condition and advised that their babies should be periodically examined. Eventually, 18 of the 28 children of chronic carrier mothers were kept under observation for 3–14 months. The results were as follows (Figure). (1) Five of the 9 cord bloods examined were HBsAg-positive. One child with HBsAg-positive cord blood was born by caesarean section (Case 4). But the positivity for HBsAg in the cord blood was transient as all the sera examined 2–3 days later were consistently HBsAg-negative. (2) In 10 (56%) of the 18 children a weak but definite positivity for HBsAb was found for the first time in the sera obtained at 1–2 months of age. None of these children had previously been HBsAg-positive, apart from 3 transient positives in cord blood (Cases 4, 9, and 14, Figure). Even the HBsAb-positivity was generally transient; only in Case 9 was it still present in the last examination at 7 months. (3) Four of the 18 children became HBsAg-positive between 2 and 4½ months. This incubation period is in agreement with previous work, suggesting that infection with HBsAg usually takes place during the immediate perinatal period. Details of these 4 cases were as follows.

Case 1. This asymptomatic infant, whose cord blood was HBsAg-positive, showed HBsAg positivity with slightly increased AST and ALT only on one other occasion at 4½ months. This positivity was transient and was followed by appearance of HBsAb at age 10 months.

Case 3. HBsAg was found for the first time at 4 months, accompanied by markedly increased AST and ALT and by slight liver enlargement without jaundice or other clinical symptoms. The raised transaminase levels persisted during the observation period (up to 14 months). A liver biopsy at 7 months showed histological features of chronic hepatitis (interstitial fibrosis with mononuclear infiltrates, with some disorganisation of the lobular architecture).

Case 11. At 2 and at 3 months this asymptomatic child, who had been previously HBsAg-negative, showed HBsAg positivity and moderately increased transaminase levels.

Case 18. HBsAg was present from age 2 months up to the last examination at 6 months. Serum transaminases were normal, and there were no clinical symptoms.

A negative correlation was found between early

positivity for HBsAb and the development of HBsAg positivity: all 10 HBsAb-positive children remained HBsAg-negative, while 4 of the 8 HBsAb-negative children became HBsAg-positive. This difference is significant at the 0·01 level by the χ^2 method.

(4) 16 of the 18 mothers were studied for HBeAg and HBeAb (Table 1). All were HBeAg-negative, while 11 were HBeAb-positive. Persistent HBsAg positivity developed, at 3 and 4 months of age, in 2 of the 5 children born to HBeAb-negative mothers, and in none of the 11 children born to HBeAb-positive mothers. Only one of these developed HBsAg positivity at age 4½ months; this rapidly disappeared and was followed by the development of HBsAb (Case 1, Figure).

This difference is significant at the 0·025 level.

(5) All the 18 HBsAg-positive mothers, including those whose children became HBsAg positive, were tested for HBcAb and found positive.

(6) Only one of the 17 fathers studied was a HBsAg carrier like his wife. The child born to this couple was positive for HBsAb at 2 and 4 months, and at 6 months he was still HBsAg-negative.

Discussion

While there may well be pronounced ethnic differences in the frequency with which HBsAg is transmitted by carrier mothers to their babies, recent studies using sensitive detection methods have shown this frequency to be quite high in all countries (Table 2).

Direct evidence of maternofetal transmission is given by the HBsAg positivity of cord blood at birth. In this respect, in agreement with other recent studies (Schweitzer *et al.*, 1973; Boxall and Davies, 1974; Papaevangelou *et al.*, 1974; Chircu *et al.*, 1975), we found a high percentage of positivity (5 of the 9 cord bloods examined). But the present study gives additional, indirect evidence of maternofetal transmission of HBsAg even in those children in whom HBsAg has not been directly demonstrated. In fact, many infants of our series, previously repeatedly HBsAg-negative by radioimmunoassay, developed antibodies against this antigen within the first 2 months of life. A postnatal infection of these infants is extremely unlikely, because of this high frequency of an early appearance of HBsAb. By adding to the subjects with HBsAg-positive cord blood those who developed HBsAb early in life, we have direct or indirect evidence of fetal infection with HBsAg in 13 of the 18 infants. We could add to these another 2 infants (Cases 3 and 18, Figure) in whom HBsAg appeared at 4½ and at 2 months, even if postnatal infection cannot be ruled out for these subjects, particularly for Case 3.

Despite this high transmission rate, only a few children (2 or 3 out of 18 in our series) developed persistent HBs antigenaemia. It is probable therefore that in most subjects there are some protective factors.

Okada *et al.* (1976), in a series of mother-child pairs recently studied in Japan, found that the children of HBeAg-positive mothers all became HBsAg-positive, while the children of mothers with HBeAb remained HBsAg-negative. More recent studies (Gerety and Schweitzer, 1977; Dupuy *et al.*, 1978) have raised some doubts about the infecting role of maternal HBeAg, while the protective role of maternal HBeAb has been fully confirmed: in these series, HBs-antigenaemia developed in only one child of a HBeAb-positive mother, but was transient and was rapidly followed by the appearance of HBsAb. Our series comprises one other child with an identical pattern, and clearly confirms that maternal HBeAb always prevents the development of chronic HBs antigenaemia in these children. As (as in the study of Papaevangelou *et al.*, 1974) all the 18 mothers of our study were HBcAb positive, the results do not suggest that maternal HBcAb prevents HBsAg infection of the conceptuses.

By contrast, a significant protective role is played by the HBsAb produced by the infant from the first weeks of life. The 3 infants who became persistently HBsAg-positive were all born to HBeAb-negative mothers, and none of them had been HBsAb-positive in the first 2 months of life. On the other hand, none of the children whose mothers were HBeAb-positive, or who themselves had been HBsAb-positive, became a HBsAg carrier.

On the basis of these results, a strategy is indicated to prevent persistent antigenaemia in children of HBsAg carrier mothers in areas with a high prevalence of HBsAg carriers. (1) Each pregnant woman should be tested for HBsAg. (2) Each HBsAg-positive woman should be tested for HBeAb. (3) Each child of an HBsAg+, HBeAb− mother is at risk and administration of HBsAg hyperimmune gammaglobulin should be considered, or (4) each child of an HBsAg+, HBeAb− mother who remains HBsAb− during the first 6 weeks of life is at risk and administration of HBsAg hyperimmune gammaglobulin should be considered.

Kohler *et al.* (1974) and Dosik and Jhaveri (1978) have suggested that a chronic HBsAg carrier state might be prevented by the administration of hyperimmune HBsAg globulins in the immediate postnatal period. A control trial of such treatment in infants selected in the above fashion could provide useful data.

Virus infections in children with acute lymphoblastic leukaemia

A. W. CRAFT, M. M. REID, P. S. GARDNER, E. JACKSON, J. KERNAHAN, J. MCQUILLIN, T. C. NOBLE, AND W. WALKER

SUMMARY The pattern of virus isolation and illness was studied in 64 children with acute lymphoblastic leukaemia (ALL) during periods of apparent infection and when the children were well. The virus isolation rate of 2·2 viruses per child a year is similar to that previously found in normal children. In only 32% of children with symptoms were viruses found and 14·5% had viruses isolated when asymptomatic. The children with ALL appear to be more vulnerable to multiple virus infections and to excrete the virus for longer periods. This may be due to failure of production of both local and systemic antibodies. The failure in the past to recognise the true importance of virus infections in ALL may have been due to inadequate diagnostic techniques.

Infections are playing an increasingly important role in the death of children with acute lymphoblastic leukaemia (ALL) and viruses are emerging as important pathogens (Craft *et al.*, 1977). While it is recognised that varicella zoster and measles may be particularly severe in the immunosuppressed host (Feldman and Cox, 1976), it has been suggested that the common upper respiratory virus infections are neither more frequent nor more severe in children with ALL (Levine *et al.*, 1974). However, there has been little systematic study of virus infections in this disease. In the present investigation viruses were studied in children with ALL, both when an infection was suspected and when the children were well. The results are presented in the light of locally acquired experience of virus infections in normal children.

Patients and methods

64 children with ALL, 34 boys and 30 girls, were followed for at least 2 months, some for as long as 33 months. Their ages at diagnosis ranged from 1½ to 14 years. All were being treated with conventional combination chemotherapy and prophylactic cranial irradiation and most were on a modified ALGB 6801 regimen (Reid *et al.*, 1977). During the initial phase of the investigation children were studied only when they were suspected of having an infection. 31 such children were followed for a total of 468 patient months. The remaining 33 children were investigated when they were infected and also routinely at monthly intervals. They were followed for a total of 397 patient months. When an infection was suspected a specimen of nasopharyngeal secretion was investigated by the fluorescent antibody technique (FAT) (Gardner and McQuillin, 1974). Nose and throat swabs were obtained at the same time and cultured for viruses. The routine monthly investigations consisted only of nose and throat swabs. Varicella zoster was identified by fluorescent antibody staining of scrapings of skin lesions. All isolations by the FAT were confirmed by subsequent culture. No attempt was made to isolate viruses from faeces or urine. Whenever possible further specimens were taken after the initial diagnosis of a virus infection until the child ceased to excrete the virus. Specimens of blood both in the acute and convalescent phases were taken from many of the patients

and the titre of complement fixing antibody to the isolated virus was determined.

The clinical features of the illnesses caused by viruses were divided according to whether or not the child was asymptomatic, had a mild to moderate illness which was not more severe than would be expected in a normal child and for which admission to hospital was not required, symptoms which were much more severe than usual requiring admission to hospital and often life threatening, and those which were associated with the death of the child although not necessarily the direct cause of death.

Controls

Control information was obtained from normal children admitted to local hospitals in recent years because of a virus infection and investigated using identical techniques in the same laboratory as in this study. A group of 796 normal children was studied to define the rate of multiple virus isolation in a single infective episode.

The length of time for which influenza A, respiratory syncytial virus (RSV), or measles was excreted by normal children was obtained by examination of follow-up specimens taken after the diagnosis of the infection. Generally no further specimen was taken after the child was clinically well or discharged from hospital.

The pattern of rise of complement fixing antibodies to influenza A and measles in normal children was obtained from the same group of children, but for RSV the control data were confined to those older than one year. However, the effect of local nasopharyngeal blocking antibodies on the rate of isolation of RSV from normal children (Gardner and McQuillin, 1978) was studied in children of all ages.

Results

During the initial phase of the investigations 31 patients were followed for a total of 468 patient months and 46 viruses were obtained, with an isolation rate of 1·2 viruses per child a year. The remaining 33 children, who were also swabbed routinely at monthly intervals, were followed for 397 patient months and 73 viruses were isolated, an isolation rate of 2·2 viruses per child a year. 119 viruses were isolated from 50 of the 64 children during 99 infective episodes. 14 were at no time infected with a virus that could be detected by these techniques. The viruses isolated and the severity of illnesses are shown in Table 1. 15 children had 21 severe illnesses associated with virus infections and clinical details of these are shown in Table 2. The 33 asymptomatic virus isolations were all made during the second phase of the study. In many of the children who had symptoms suggesting a virus infection it was not possible to isolate one, and the relationship between the presence of symptoms and the isolation of virus is shown in Table 3.

18 children had more than one virus isolated during the same illness, 15 had a dual infection once, 2 on two occasions, and 1 child had three viruses isolated simultaneously. Multiple virus isolations were therefore present in 20 (20%) of the 99 episodes of virus infection. There were 20 multiple virus isolations in the 796 normal children, a rate of 2·5%. This difference is significant ($\chi^2 = 66{\cdot}5$, $P<0{\cdot}001$).

The length of time of excretion of RSV, influenza A, and measles is shown in Fig. 1 and is compared with data from normal children.

The antibody titres to RSV, influenza A, and measles during the acute and convalescent phases of the illness are compared with those from a group of normal children in Fig. 2.

Table 1 *Viruses isolated according to the severity of illness*

Isolated	86	33
Not isolated	185	183

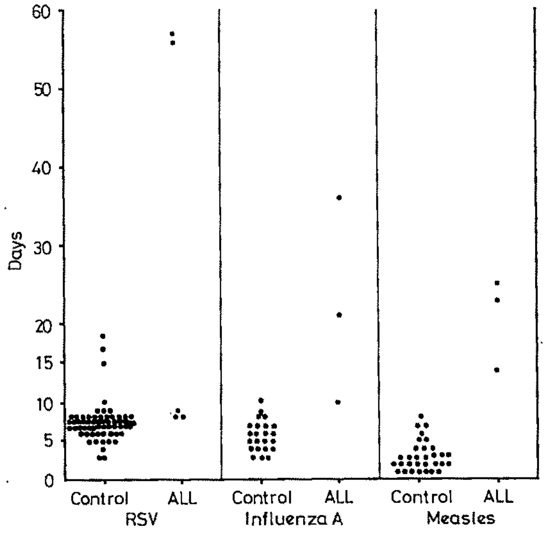

Fig. 1 *Length of excretion of RSV, influenza A, and measles virus in normal children and those with leukaemia.*

In the 5 children with RSV in whom follow-up specimens were taken it was possible to grow the virus as well as to demonstrate it by the FAT. However, of 150 normal children in whom RSV was demonstrated by the FAT in a follow-up specimen it was possible to grow the virus in only 59.

Discussion

There is very little information about the incidence of virus infections in normal children. Hurrell *et al.* (1971) studied two normal families at weekly intervals for a period of almost 2 years and found a virus isolation rate in the children of 2·3 viruses per child a year. The only other reported survey of virus infections in normal children is from the Seattle Virus Watch Programme but it is difficult to obtain a clear picture of virus isolation rates (Elveback *et al.*, 1966). The isolation rate of 2·2 viruses per child a year, during the second phase of the current study suggests that children with leukaemia may not be more susceptible than normal children to virus infections, although the isolation rate might have been higher had they been swabbed at weekly intervals. However, previous studies have included many children less than one-year old, whereas most of the children with ALL were considerably older than this. Young children are known to suffer from more respiratory infections than older ones (Miller *et al.*, 1974). Until more is known about viruses in the normal population it will not be

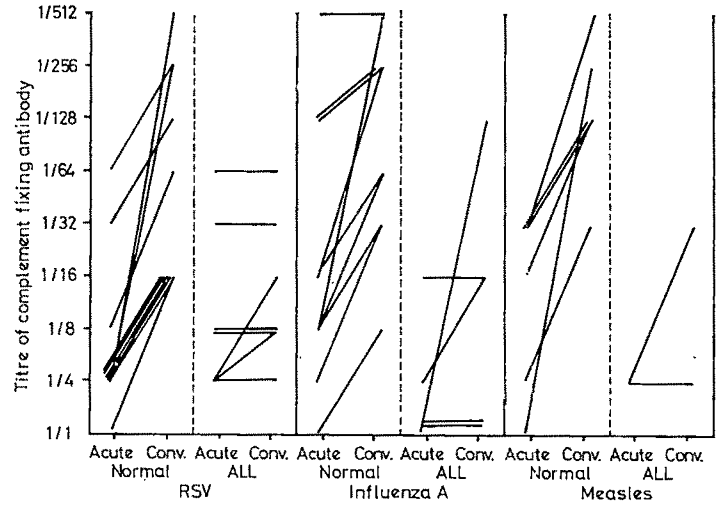

Fig. 2 *Titre of complement fixing antibody to RSV, influenza A, and measles virus in acute and convalescent phases of illness in normal children and those with leukaemia.*

possible to be certain about the susceptibility of children with ALL to these infections.

The isolation of viruses from asymptomatic children, and the failure to isolate a virus from an apparently infected child, are both well recognised phenomena (Elveback *et al.*, 1966). Elveback suggested that asymptomatic infections and excretion of virus were more common in younger than in older children. In the present study a virus was isolated from only 32% of the children with symptoms suggesting a virus infection. A virus was isolated from 15·3% of the routine swabs taken from asymptomatic children. It is difficult to compare these results with those obtained from the Seattle Virus Watch Programme because of differences in the techniques used for isolation and, in particular, because faecal specimens were also collected in the American study. However, it is clear that many children suffer upper respiratory tract infections whose cause, at present, remains unknown and also that apparently well children may be asymptomatic carriers of, in particular, cytomegalovirus, herpesvirus, and rhinovirus. Many of the illnesses were no more serious than similar virus infections in normal children. However, severe illnesses, which were often life threatening, were associated with 25 of the viruses isolated. Many of these children had prolonged illnesses necessitating interruption of their leukaemia treatment.

Nine viruses were associated with 6 deaths. The role of viruses in the death of children with ALL has been discussed in detail (Craft *et al.*, 1977).

Concurrent multiple virus isolations appear to be more common in children with ALL than in normal children, and this aspect of the study is being reported in detail elsewhere (Bruce *et al.*, 1979). The apparently increased susceptibility of children to multiple virus infections may be associated with prolonged excretion of viruses in many cases. Most normal children who have measles will have ceased to excrete virus by 3 or 4 days after the appearance of the rash and in a review from this laboratory none excreted for longer than 10 days (McQuillin *et al.*, 1976). Influenza viruses are not normally excreted for more than 9 days in children (Brocklebank *et al.*, 1972) and for only 3 or 4 days in adults (Knight *et al.*, 1970), whereas the children with ALL did so for much longer. Most children with RSV stop excreting the virus by 10 days. Although there is a great deal of information about RSV in normal children in Newcastle, much of this has been acquired from infants less than one-year old (Gardner, 1976). Older children rarely develop infections severe enough to require admission to hospital and they also excrete the virus for a shorter period of time than do infants (Hall *et al.*, 1976). All the children with ALL were older than one year, but some developed severe infections similar to those seen in normal infants. One child in the present study continued to excrete RSV for 56 and 57 days in two separate infective episodes one year apart. Rhinoviruses may be excreted for prolonged periods in normal children (Fox *et al.*, 1975) as was found in the children with ALL.

Changes in complex immunological mechanisms probably account for the increased severity and prolonged excretion of viruses in children with ALL. In the current study we have been able to look at two aspects of the immune system. In only 59 of 150 children in whom RSV was demonstrated by the FAT was it possible to grow the virus. Complex immunofluorescent staining techniques have shown that this is due to the production of local blocking antibodies which prevent replication of the virus but do not prevent its demonstration by the FAT (McQuillin *et al.*, 1970; Gardner and McQuillin, 1978). In the 5 children with leukaemia and RSV infection, follow-up specimens were all positive by both the FAT and viral culture and it was not possible to detect any local blocking antibodies. This failure of production of antibody to RSV is also shown serologically. Fig. 2 shows that all normal children with this infection produced a significant rise in the titre of complement fixing antibodies, compared with only 2 out of the 7 children with ALL. However, the situation with regard to other viruses is not as obvious and that for measles is complicated by the administration of pooled immunoglobulin. Borella and Webster (1971) reported impairment of the immune response to viral infection in patients with leukaemia. Bosu *et al.* (1975) studied the antibody response to polio virus immunisation in children with leukaemia and demonstrated a uniform failure of IgM response which they felt was independent of the leukaemia treatment, since it was still present in children in whom treatment had been stopped for at least 6 months.

The diagnosis of a viral infection has in the past depended to a large extent upon the demonstration of a rise in the titre of specific antibodies. The antibody rise which occurs in normal children may not occur in children with leukaemia, and this may have resulted in the past in the failure to recognise the true importance of virus infections in leukaemia.

We are grateful to the Tyneside Leukaemia Research Association for financial support.

Bacteriological monitoring of unheated human milk

D. C. DAVIDSON, R. A. POLL, AND C. ROBERTS

Special Care Baby Unit, and Regional Public Health Laboratory, Fazakerley Hospital, Liverpool

SUMMARY To assess the bacteriological quality of unpooled expressed breast milk, a pilot bottle sample of each donation was examined before the milk was given to the neonate. Provided the milk did not contain >2500 organisms/ml or potential pathogens it was used unheated. Milk containing between 2500 and 5000 organisms/ml and no potential pathogens was used after pasteurisation. Using these criteria, 67% of 460 donations were acceptable. However, because the bacteriological quality varied, 45% of domiciliary donations were discarded compared with only 29% of those from hospital.

Breast milk composition differs from cows' milk and artificial formulae in many important aspects. Some of these were described in the report from the Department of Health and Social Security (1974) which recommended that breast feeding should be encouraged. While human milk is generally accepted as ideal nutrition for term neonates, the composition varies and may not represent optimal nutrition for preterm infants and those of low birthweight. Davies (1977) showed that such infants fed artificial formulae had better rates of growth than those fed expressed breast milk. Nevertheless the importance of human milk to the young infant derives not only from its nutrient content but also from its 'anti-infective' properties. Lactoferrin, an iron-binding protein, is important in the prevention of infection by *Escherichia coli*; B_{12} and folate-binding proteins which limit the availability of these vitamins for bacterial growth are also important. Specific IgA immunoglobulin acts in the neonatal gut and limits the growth and reproduction of bacterial and viral pathogens. Maternal antibodies, cellular content, bacteriostatic enzymes, lysozyme, and nonpathogenic bacteria further contribute to the anti-infective properties of human milk.

Carefully controlled pasteurisation reduces the damage to the humoral components of human milk, whereas higher temperatures not only destroy vegetative bacteria but can adversely affect the anti-infective properties and alter the chemical composition of the milk (Ford *et al.*, 1977; Williamson *et al.*, 1978).

In 1976 it was decided to examine the possibility of providing unheated, unpooled human expressed breast milk at this hospital for the nutrition of low birthweight babies, especially neonates in the intensive care unit, provided the bacteriological quality met our standards. Our experience of the bacteriological monitoring and provision of raw human milk is described.

Materials and methods

Only mothers who were free of communicable disease (for example, tuberculosis, respiratory infection, enteric, skin, or breast infection) and those not on drugs transmissible via breast milk were accepted as donors.

During a 2-year period (1976–78) samples of expressed breast milk (EBM) from hospital and from women at home were examined. All mothers received instruction on breast and hand hygiene and on the technique of manual expression of the breast, although most hospital specimens were obtained by the breast pump. After the EBM had been collected into autoclaved 100 ml glass bottles, approximately 2 ml milk was decanted into a sterile pilot bottle for bacteriological screening (Fig. 1). Those specimens collected in hospital were deep frozen to −20°C in the breast milk bank freezer as quickly as possible, often within a few minutes of collection. Specimens from home were stored in the ordinary compartment of the domestic refrigerator (not deep frozen) and taken to the breast milk bank in an insulated cool box every 48 hours by the donors themselves or by domiciliary midwives. On receipt at the hospital milk bank these domiciliary donations were then also stored at −20°C. Each bottle was stored separately and *not* pooled before freezing. Donations varied in volume between 50 and 100 ml

and did not remain in the bank for more than a few days because of the demand for human milk. Before milk was issued, the pilot bottle was removed, allowed to thaw at room temperature, and then bacteriologically screened. This usually took less than 24 hours and no raw specimen of breast milk was used until bacteriologically acceptable. When clearance was given the donation was allowed to thaw at room temperature and issued for feeding. Thawed specimens were stored in the domestic compartment of the refrigerator in the intensive care unit until needed. Any thawed specimen not used after 12 hours (although rare) was discarded to reduce risk of bacterial contamination and denaturation.

The pilot bottle of milk was examined soon after receipt in the laboratory. Total quantitative bacterial counts on unheated samples were performed in duplicate using 10 drops from a standard 50-dropper pipette on a 1 in 5 dilution of milk in 1 in 4 strength Ringer's solution, whereas pasteurised milk was examined undiluted to increase the chance of isolating organisms which would be present in smaller numbers than in unpasteurised milk. In both instances, the milk was inoculated on to 10% horse blood agar, MacConkey agar, 0·03% cetrimide agar, and nutrient agar containing 8·5% sodium chloride to facilitate the screening of organisms potentially detrimental to the safe use of milk. The sensitivity of the quantitative method meant that the minimum bacterial count detectable in unheated milk was 25 organisms/ml and in pasteurised milk it was 5 organisms/ml. Arbitrary criteria applied to the EBM samples were: (1) Milk with a quantitative count of <2500 organisms/ml (Wright, 1947) (consisting of, for example, micrococci, *Staphylococcus albus*, 'viridans type' streptococci, or diphtheroids which were considered to be contaminants probably derived from skin flora but unlikely to be pathogenic) was used unheated. (2) No donation was used unheated or pasteurised if the pilot bottle gave either a total count >5000 organisms/ml or any detectable potential pathogen. On an arbitrary basis the potential pathogens were defined as *Staphylococcus aureus*, β-haemolytic streptococci, *Pseudomonas* spp., *Proteus* spp., *Streptococcus faecalis*, and any other organism from a potential enteric or water-borne source (here defined as 'coliforms' for convenience). (3) No donated milk with a total bacterial count of 2500–5000 organisms/ml was used unheated. If the pilot sample had a bacterial count in this range, but none of the organisms listed in (2), the donated milk was pasteurised at 63°C for 30 minutes in a water bath and subjected to the same bacteriological screen, plus the alkaline phosphatase test. (Alkaline phosphatase is destroyed by a temperature of 63°C within 30 minutes and is used as evidence of adequate pasteurisation of cows' milk). Provided effective pasteurisation was established by no detectable growth on culture and a satisfactory phosphatase test, the milk was issued for use.

Results

The overall distribution of the bacterial counts of the EBM over the 2-year period is shown in Fig. 2. Clearly most EBM samples had low counts and the distribution shows gradually diminishing numbers of specimens up to 36 000 organisms/ml. Although there were 33 (4·5%) specimens with counts >50 000 organisms/ml, most (95·3%) specimens gave counts of <25 000 organisms/ml. A pilot investigation of anaerobic culture gave no additional information and was therefore stopped.

Of 688 raw EBM samples examined during the period, 513 (75%) came from hospital and 175 (25%) were domiciliary donations (Table 1). Within the three ranges of bacterial counts the figures for hospital and domiciliary isolates were similar—that is 460 (67%) of EBM samples gave counts of

*Allowance has been made for 43 specimens discarded which had excessive counts and potential pathogens.

<2500 organisms/ml, and 66 (9·6%) specimens gave counts of 2500–5000 organisms/ml and were pasteurised if no pathogen was present. Overall 162 (24%) were immediately discarded without pasteurisation because of counts >5000 organisms/ml. Therefore, 526 (76%) EBM specimens had acceptable quantitative bacterial counts, but some of these had potential pathogens. The main pathogens isolated were *S. aureus* and 'coliforms', but there was a difference in the total number of isolates and in the type of organism from home and hospital donations. Altogether 49 (9·6%) of 513 donations from hospital were discarded, compared with 60 (34%) of 175 from homes. *S. aureus* was isolated from 23 (4·5%) of hospital donations and from 5 (3%) of home donations, whereas 'coliforms' were isolated from 21 (4·1%) of hospital and from 32 (18%) of domiciliary collections. There was no particular relationship between quantitative counts and potential pathogens, and overall the pathogens were distributed throughout the three quantitative ranges (Table 2).

Of the EBM donations with counts in the ranges of <2500 and 2500–5000 organisms/ml, 51 (7·4%) and 15 (2·2%) of them respectively had potential pathogens and were discarded without further processing. Another 43 (6·3%) were discarded because they had excessive bacterial counts and potential pathogens.

The total number of EBM donations discarded because of excessive bacterial counts or the presence of potential pathogens was 228 (33%) (Table 3). The remaining 460 (66%) were acceptable because they contained no potential pathogen or excessive bacterial counts, as defined above, within the technical limitations of the methods employed.

Discussion

Like others, we experience difficulties in deciding what bacteriological criteria should be adopted to make EBM donations safe to give to neonates. We adopted arbitrary criteria based on such information as we could obtain. There appeared to be no widely agreed standards on the quantitative and qualitative content of human breast milk and no universally adopted figure for acceptable bacterial quality of EBM. There are no general guidelines on what are considered to be potential pathogens and the likely numbers of such species which are considered harmful to neonates. There are opposing views on the benefits conferred on babies fed raw or pasteurised milk as well as conflicting results on babies fed artificial milk as opposed to EBM.

Nevertheless we decided to investigate the quantitative and qualitative bacteriology of EBM submitted to our maternity unit. It is not possible to give precise ranges of acceptable counts or to investigate which organisms constitute an unacceptable hazard to neonates, particularly those undergoing intensive care. The criteria we adopted, although arbitrary, were necessarily stringent in order to protect our neonates from any hazard of milk-borne bacterial disease. Even with these strict criteria we were still able to issue 67% of donated EBM, a figure similar to that of Williamson *et al.* (1978). Overall only 29% (150 of 513) of hospital donations were discarded compared with 45% (78 of 175) of domiliciary collections because their bacteriological quality was either quantitatively or qualitatively unacceptable. We feel that probably the collection procedure of the domiciliary EBM was the main cause for 45% of samples being unacceptable. If the donation was unsatisfactory the donor was again visited and given further advice about hygiene by the domiciliary midwife. To some extent this was done in the case of unsatisfactory hospital donations but an additional factor was the inadequate cleaning of the breast pump and related equipment. This defect was also noted by Liebhaber *et al.* (1978) who recommended manual expression of milk, thereby reducing the need for pasteurisation. Our figures also reflect the difference caused by lack of supervision of domicilary collections, and if a neonatal unit relies heavily on domiciliary donations, closer supervision is necessary or it may be advisable to pasteurise all domiciliary donations. We should stress that our policy was devised to control the quality of the EBM and the whole procedure of collection, storage, etc. up to the time of feeding the neonate. The use of the pilot bottle provided us with a representative sample of EBM. We feel that if the donations had been pooled, even after being bacteriologically cleared, it would have added another factor to the procedure, with its attendant risks.

We did not attempt to assess the immunological or the nutritional benefits of using unpooled, unheated EBM, but we did try to assess clinically whether there was any hazard of infection. Clearly this is arbitrary, but we did not detect evidence of infection due to any of the organisms considered above in any baby fed EBM. We believe this was because EBM with potential pathogens was not used and also because EBM containing by definition nonpathogens <2500 organisms/ml does not expose the baby to any risk. In fairness it should be said that if any baby is ill because of infection by an alleged nonpathogen (referred to earlier), it is extremely doubtful if the source of these ubiquitous organisms could be identified since they do not have a generally reliable marker system.

As a result of our experience in collecting and monitoring EBM, we have decided to continue to rely on raw EBM by fostering good hygiene technique which in most specimens yields low bacterial counts (Fig. 2). As a further safeguard, bacterial monitoring will exclude any donation of unsatisfactory quality. The development of this policy resulting from the ever pressing demand in our neonatal unit for EBM has led us to review our criteria in the light of these results and of other published work. We have considered the possibility of relaxing the quantitative criteria alone so that donations with higher bacterial counts (that is, those with >2500 organisms/ml) but no potential pathogens could be safely used. There is currently no generally agreed upper quantitative limit of likely nonpathogens, although most workers agree that it is inadvisable to use EBM containing potential pathogens. Ikonan and Maki (1977) used donations with counts <20 000 organisms/ml (some after heating) and discarded only 5% of all donations. If we had applied these criteria to our results in Fig. 2 we would have discarded only 10% of EBM donations on a quantitative basis alone. We are unwilling to accept EBM donations containing potential pathogens as we feel these could present unnecessary hazards to a vulnerable group of babies, particularly those undergoing intensive care. Milk containing bacteria which may be derived from a faecal origin is clearly unacceptable and these markers are used to exclude the possibility of contamination by enteric bacteria and viruses.

Breast feeding by a mother of her own normal baby will expose that baby to his own mother's bacterial flora which quantitatively may be >2500 organisms/ml, some of which may be potentially pathogenic. It is believed by some that these are probably less hazardous than the organisms from an unrelated milk donor, because a mother secretes antibodies in her milk which reflect her own immunological experience (Gunther, 1978).

As a result of the renewed interest in breast feeding and breast milk banks, attention has been given to the advantages and disadvantages of processing EBM. Because of the fear of contaminating EBM, attention has been directed to measures which provide a bacteriologically safe milk which still retains its immunological properties (*British Medical Journal*, 1977). However enterotoxins produced by certain bacteria—for example, *S. aureus* have caused outbreaks of food poisoning due to contaminated cows' milk (Wilson and Miles, 1975)—and since the enterotoxin is to some extent heat resistant it is theoretically possible that even pasteurised human milk, although free from bacteria, may contain enterotoxin.

In addition, because the alkaline phosphatase of human milk is 40 times lower than cows' milk (Heyndrickx, 1962) the phosphatase test as applied to the latter may not be sufficiently sensitive as an indicator of adequate pasteurisation of EBM. Therefore, although rigidly controlled conditions safeguard the pasteurisation process, bacteriological quality control criteria can provide a final check of effective pasteurisation.

Milk rendered safe by boiling or even by carefully controlled pasteurisation appears to reduce levels of immunoglobulin, lactoferrin, lysozyme, and complement C3 factor (Ford *et al.*, 1977; Evans *et al.*, 1978), as well as certain nutrients (Williamson *et al.*, 1978), although Raptopoulou-Gigi *et al.* (1977) in Edinburgh found that pasteurisation did not materially alter levels of IgA or lactoferrin. Total lymphocyte counts were also significantly decreased after pasteurisation (Liebhaber *et al.*, 1977). These findings indicate the reduction of anti-infective properties of EBM with pasteurisation, and by avoiding this procedure we feel that unheated EBM of acceptable bacteriological standard provides a practical alternative for a baby in place of its own mother's milk. However, in spite of the advantages of the immunological content of nonpasteurised EBM we agree with Lucas *et al.* (1978) that it cannot be recommended for all special care baby units unless there are certain quality control safeguards.

Milk macrophages tend to adhere to the walls of the glass container and therefore simple storage may reduce the lymphocyte content. Moreover, Pitt (1976) suggested that freezing of milk will markedly diminish the number of viable cells and it must be admitted that either of these factors could have reduced the effective immunological value to our babies. Quantitative examination of the noncellular components of milk deep-frozen for 3 months at −20°C had no appreciable effect on levels of lactoferrin, lysozyme, IgG, IgA, or C3 complement component (Evans *et al.*, 1978). Repeated freezing and thawing would be expected to lead to reduction of these levels because of denaturation, but in our milk bank the process only happens once.

While cellular transfer in the breast milk from the natural mother may confer immunological advantages to her baby, it may be potentially harmful in an unrelated baby. Beer and Billingham (1975) reported a wasting syndrome similar to a graft v. host disease when neonatal rats were fed on the milk of an unrelated rat. Further work is needed to find out if this observation is important to human studies on unheated EBM.

We thank Professor Rosalinde Hurley of Queen Charlotte's Hospital for her help, the hospital and district midwives for their assistance, and Ms Angela Parry for clerical assistance.

Lost to follow up

A study of nonattendance at a general paediatric outpatient clinic

NICOLAS A. COOPER AND MARGARET A. LYNCH

Department of Paediatrics, Guy's Hospital Medical School, London

SUMMARY 50 children defined as persistent outpatient nonattenders were compared with 50 children who regularly attended the same clinics. Several factors were more often found in the group of nonattenders: (a) initial referral via casualty without a letter from the family doctor, (b) hospital admission before the first outpatient appointment, (c) recognition of multiple medical problems, and (d) evidence of diffuse social problems affecting the family. 34 of the nonattenders had at least 2 of these factors, compared with only 9 children in the other group. Many of these problems can be identified at the initial consultation, and perhaps other methods of continuing health care should be provided for these children.

One traditional way that continuing paediatric care is given is by way of a hospital outpatient department, but nonattendance at such clinics is common (Drachman *et al.*, 1969; Alpert *et al.*, 1970; Anderson *et al.*, 1971).

This study examines the problem of nonattendance at a general paediatric outpatients department and investigates whether the persistent nonattenders form a clearly defined group. The clinics from which the patients came were those held in the main outpatient department of a busy teaching hospital serving a typical inner city area with poor social and environmental conditions, a high rate of unemployment, and a large immigrant population. Within the hospital there is a paediatric casualty department and traditionally this is seen by the local population as a source of primary health care. The study was performed at a time of year, April to June, when neither poor weather conditions nor holidays could be blamed for a low attendance.

Patients and methods

During the study period 600 appointments were made for children at Guy's Hospital general paediatric outpatient clinics. These clinics took place on Wednesday, Thursday, and Friday mornings each week. The overall nonattendance rate was 25%. About one-third of these were persistent nonattenders defined as those children who failed to attend on a particular day, who had been given at least 4 appointments, and failed 2 consecutive appointments, or more than 25% of them. Most nonattenders came from Lambeth, Southwark, or Lewisham AHA (T), and this study was restricted to children whose families were resident in these areas. A group of 50 nonattenders was compared with a group of 50 regular attenders. The regular attenders had been given appointments on the same days as the nonattenders, and had previously been given 4 or more appointments, attending more than 75 % of them, and never missing 2 consecutive appointments.

Information about the children was obtained from hospital records including neonatal, paediatric, casualty, and social work notes. We obtained information about social and family background, and looked in detail at the child's medical history, and at the family's current and past social problems. If appropriate, further information was obtained from the Social Services Department, the Community Health Services, or directly from the parents. Several home visits were made to gain further information and to discuss possible reasons for nonattendance.

Statistical evaluation was carried out with the χ^2 test.

Results

Child.

Sex

There were 32 boys in the group of nonattenders compared with 30 in the control group.

Queen Elizabeth Hospital for Children, London
NICOLAS A. COOPER, senior house officer
Department of Paediatrics, Guy's Hospital Medical School, London
MARGARET A. LYNCH, senior lecturer in community paediatrics

Age

There was little difference between the ages in the two groups. Nearly half the children in both groups were under 5 years.

Length of follow-up

The length of follow-up varied from a few months to several years. The slightly higher proportion of nonattenders (64%) followed up for less than 12 months, compared with 42% in the other group did not reach statistical significance ($\chi^2 = 4{\cdot}86$, $P>0{\cdot}02$).

Family background

Social class

In both groups most of the families were in social class IV or V (Registrar General's classification). There was little difference between the numbers of unsupported mothers in the two groups. However, all the 6 unemployed fathers belonged to families of nonattenders (Table 1).

Ethnic group

24% of nonattenders and 12% in the control group had parents whose country of origin was outside the United Kingdom and Ireland (Table 2).

Housing

70% of families in both groups were living in local authority housing. This is only slightly higher than the rate for the local population.

Family structure

The families of both groups were of similar sizes (Table 3). There were 124 children in the families of nonattenders and 126 in the other group (Table 4). The control group families appeared to have a higher proportion of children over age 16 years: 22% compared with 13%. Three nonattenders and 2 children in the control group each had 2 siblings under 5 years.

	1	*2*	*3*	*4 or more*
Nonattenders	16	12	11	11
Control	12	18	7	13

Table 4 *Ages of children in family*

Group	*0–5 years*	*6–15 years*	*16 years*	*Total*
Nonattenders	38	70	16	124
Control	32	66	28	126

Contact with the hospital.

Method of referral

For 64% of the nonattenders the initial contact with the hospital had been in the casualty department without a referring letter. Significantly fewer (22%) of the control group presented in this way ($\chi^2 = 17{\cdot}99$, $P<0{\cdot}001$). The casualty attendance led to the child being admitted for 25 nonattenders and 6 control children. The majority (64%) of the control group had been referred to the hospital by their family doctors and, with the exception of 2, directly to the outpatient department.

The routes of initial referral to outpatients are summarised in Table 5. Far more (50%) of the nonattenders had their first outpatient appointments made as the direct result of admissions to hospital ($\chi^2 = 11{\cdot}57$, $P<0{\cdot}01$).

Initial referral diagnosis

There was no great difference between the two groups in the reason for referral. More than 30% of

Table 1 *Social class**

Group	*Casualty*	*Casualty and ward*	*GP*	*GP and ward*	*Labour ward*	*Other hospital*
Nonattenders	7	25	15	0	3	0
Control	5	6	30	2	3	4

children in both groups were referred because of respiratory tract disorders. 13 nonattenders were admitted with respiratory tract disorders compared with only 3 children in the control group.

Subsequently identifiable problems
During the period of hospital contact 22 nonattenders were recognised as having further medical problems, compared with only 8 children in the other group ($\chi^2 = 9\cdot33$, $P<0\cdot01$). Nearly half of these problems were either of a psychiatric or a psychosocial nature—for example behaviour problems, enuresis, school refusal.

Of the 22 children with subsequently identifiable problems, 5 were found to have multiple problems during the follow-up period. For example, one child was first seen in outpatients department after hospital admission for an episode of wheezy bronchitis at age 4 months. During the period of intermittent attendance further problems became apparent: failure to thrive, behaviour problems, and the possibility of child abuse.

Hospital admissions
There was no difference in the number of hospital admissions for the two groups of children during the period of outpatient follow-up. More than 40% of children in both groups were admitted to hospital during this period. Of these, about a quarter had at least 4 admissions.

Casualty attendance
60% of nonattenders and 62% of the control group did not visit the casualty department during the last 3 years of follow-up. 8% in both groups made at least 10 visits.

Growth
There was no difference in the weight or height of the children in either group. Approximately 15% of children were <10th centile for either height or weight.

Neonatal concern
Records were examined to see if any medical concern had been noted in the neonatal period—for example admission to a special care baby unit, low birthweight, prematurity, prolonged jaundice, apnoeic attacks.

Although there was a suggestion that more nonattenders (14) had neonatal problems than control children (9), this was not significant.

Contact with social services.

74% of families from the group of nonattenders were known to the social services, either within the hospital or in their local area, during the period of follow-up. Many were actively concerned with the social services at initial referral. Only 38% of families from the control group were in contact with social services ($\chi^2 = 13\cdot15$, $P<0\cdot001$).

Social work problems can be divided into defined and diffuse (Lynch *et al.*, 1976). Defined problems are isolated ones in otherwise stable families—for example housing, practical help with the care of the children, assistance with the emotional difficulties of the child's illness. Diffuse problems are those in which a number of long-term problems beset the whole family. For example, one family was being helped by the social services because of poor housing conditions. However, it soon became apparent that there were numerous other problems. The father had been unemployed for 2 years, there were massive rent arrears, a sibling of the nonattender was a school refuser, and when one of us (N.A.C.) visited the family he found the outpatient appointment cards propping up the hi-fi record deck.

Using this classification, families known to social services were allocated to either a defined or diffuse category. 78% of the families of nonattenders and 42% of the control group receiving social work help were considered to have diffuse social problems ($\chi^2 = 7\cdot37$, $P<0\cdot01$). Thus 58% of all the children who were nonattenders came from families who had diffuse social problems while only 16% of the control group came from such backgrounds ($\chi^2 = 18\cdot98$, $P<0\cdot001$).

Two of the children in the group of nonattenders were on the 'at risk' register at the time of failed follow-up.

Adverse factors.

Four factors were significantly more often present in the group of nonattenders: (a) initial referral via casualty, without a letter from the family doctor, (b)

Table 6 *Total number of adverse factors*

Group	*0*	*1*	*2*	*3*	*4*
Nonattenders	8	8	13	12	9
Control	30	11	6	2	1

hospital admission before the first outpatient appointment, (c) recognition of multiple medical problems, (d) evidence of diffuse social problems affecting the family. The distribution of these factors is shown in Table 6. There is a pronounced accumulation of 'adverse' factors in the group of nonattenders, 34 children having at least 2. Only 9 control children had more than one factor.

Discussion

American studies suggest that nonattendance at outpatients departments is common (Drachman *et al.*, 1969; Alpert *et al.*, 1970; Anderson *et al.*, 1971). It would seem that this is equally true here in an inner-city area, with 25% of appointments not being kept. However, this is still better than the nonattendance rate in general paediatric clinics in the USA, where 40% of appointments are missed (Anderson *et al.*, 1971). One-third of the nonattenders at the Guy's clinic persistently failed to appear. This persistent failure to attend was unrelated to the child's age, sex, ethnic origin, or the family's social class. However, all the children with unemployed fathers were nonattenders.

A large young family is likely to make it more difficult for a parent to bring a child to the outpatients department. While there were no fewer preschool siblings in the control group, there was a suggestion that overall these families, while being of similar size, were older as 22% had at least one child over age 16, compared with 13% in the families of nonattenders. Unfortunately parental ages were not always recorded but it may well be that the parents of persistent nonattenders were younger and less experienced. Many of the nonattenders (64%) were referred from casualty without referral letters from their family doctors, and half of them were admitted to hospital before their first outpatient appointments. This suggests that these parents only seek urgent medical advice when their children have acute illnesses. The fact that many of the diagnoses on admission were of illnesses often treated at home—for example otitis media, upper respiratory tract infections, mild wheezy bronchitis—suggests that other factors may have influenced the decision for admission. In a recent survey in Nottingham, lack of home facilities and parental capacity was judged to be the main factor in the decision to admit a child in 20% of cases (Wynne and Hull, 1977).

Although the initial diagnoses were similar in the two groups, there was evidence that the families of nonattenders subsequently developed multiple problems of both a medical and psychosocial nature. Although unrecorded at the time it seemed that many of these problems were present at the initial referral.

The children who persistently failed to attend not only had multiple medical problems, but also came from families with diffuse social problems (58%). Many of these children were already known to the social services at the initial referral, and this may have influenced the decision to admit to hospital when first seen in the casualty department.

Many of the nonattenders needed continuing health care, as shown by the number of admissions to hospital during the follow-up period. This was very similar in both groups with 10% of children requiring at least 4 admissions.

It appears from the evidence presented in this study that children who persistently fail to attend outpatients form a definable group. They tend to have diffuse medical and social problems, and their parents tend to view minor acute illnesses as requiring urgent medical attention, yet fail to seek long-term medical care. There is a need to explore other ways of providing health care for children whose parents persistently fail to bring them to hospital for follow-up.

It has been suggested that if a visit is made to the home shortly before the hospital appointment the child is more likely to attend, but this appeared to be partly related to providing transport to the hospital (Anderson *et al.*, 1971). Of 12 families visited at home in this study, none viewed transport as a major obstacle to their ability to attend, and indeed many resided within easy walking distance of the hospital. A social worker could well help to plan the family's visit to the hospital and might improve attendances and give a valuable opportunity for a joint discussion of the family's interrelated medical and social problems.

It has been shown that nonattenders at community child health clinics are similar to those described here (Ford, 1976). However, in this sample several families attended child health clinics or used a day nursery although they failed to use either hospital services or their family doctors on a regular basis. Follow-up might well be successfully carried out in the community with help from the health visitor and social worker. A united effort by both community and hospital services to encourage parents to take their children to a single clinic is likely to be much more successful than uncoordinated attempts to make them attend a variety of different agencies.

The study was partly supported by The Guy's Trustees.

We thank staff from the casualty, social work, and obstetric departments whose notes and information made this study possible, and also the staff from the Community Health Services, Castle House, London SE1. We are grateful to Professor R. J. Robinson for his interest and encouragement, Dr C. Chantler and Dr Leo Stimmler for permission to include families under their care, and Mrs D. Dean for secretarial help.

Oral fat loading test

A reliable procedure for the study of fat malabsorption in children

A. JONAS, S. WEISER, P. SEGAL, AND D. KATZNELSON

Department of Paediatrics 'A' and the Metabolic Unit, Chaim Sheba Medical Centre, Israel

SUMMARY Oral triglyceride (TG) loading tests were performed in four groups of children: normal controls, patients with chronic nonspecific diarrhoea (CND), biopsy-proved mucosal pathology (MP), and disturbed intraluminal fat malabsorption (IFM). The rise of plasma TG levels ≥ 55 mg/100 ml ($\geq 0\cdot6$ mmol/l) can discriminate between patients with gastrointestinal disease and normal controls or patients with functional disturbances. The postmeal plasma TG rise correlates well with the coefficient of fat absorption (CFA) in normal subjects, patients with CND, and patients with IFM, but not in patients with MP who showed a disproportionally low plasma TG rise compared with their CFA. This test can serve as a useful tool in diagnosis and clinical evaluation for children with gastrointestinal disorders.

The evaluation of fat absorption is based mainly on balance studies, measuring intake and output over a particular period. The technical difficulties, especially that of reliable stool collection, have limited the use of this method. Other techniques using loading tests of iodine-labelled (Barbieri *et al.*, 1968) or ^{14}C-labelled fat (Shigekoto and Wagner, 1968) depend on accurate urine or expired air collections and pose similar problems. Plasma triglyceride (TG) increase after oral fat load has been found useful in evaluating fat malabsorption in children with a variety of gastrointestinal diseases (Norman *et al.*, 1971; Fällström *et al.*, 1977). The reliability of this method to determine various degrees of fat malabsorption has not yet been investigated, nor has this method been used in children with chronic nonspecific diarrhoea (Davidson and Wasserman, 1966).

We used the oral fat load to evaluate the correlation between the rise in plasma TG after a test meal and the coefficient of fat absorption in various disorders, including that of chronic nonspecific diarrhoea.

Patients and methods

21 children with no gastrointestinal symptoms aged between one month and 14 years were compared with three groups of patients: (a) 14 children aged between 5 months and 8 years with chronic nonspecific diarrhoea (CND) and normal or transiently delayed weight gain, in whom no gastrointestinal disease could be shown; (b) 17 patients aged between 4 months and 14 years with biopsy-proved intestinal mucosal pathology (MP). This group comprised 13 patients with gluten-sensitive enteropathy, and 4 babies with postgastroenteritis malabsorption; (c) 12 patients aged between one month and 8 years with intraluminal fat malabsorption (IFM), This group comprised 7 patients with cystic fibrosis and 5 children with bacterial overgrowth as shown by duodenal fluid culture.

Fat was determined on 72-hour stool collections using a gravimetric method (Jeejeebhoy *et al.*, 1970). In small children stools were collected with the aid of metabolic frames. Fat intake was measured during the collection period and the coefficient of fat absorption (CFA) calculated according to the formula: (fat intake − fat output) × 100/fat intake. The TG loading test was performed after a 6-hour fast in small children and after a 12-hour fast in older ones. The meal consisted of Blue Band margarine, 2 g/kg, mixed with cocoa powder and saccharine, to form a cream of acceptable taste. The fatty acid composition of this margarine is 19·5% saturated (12%-palmitic, 7·5%-stearic), and 80·5% unsaturated (43·8%-oleic, 32%-linoleic, and 4·7%-linolenic). Small babies and reluctant toddlers were intubated. In the latter case the mixture was melted to a maximum temperature of 60°C. Blood was

drawn at periods of 0, 2, and 4 hours after fat ingestion. Plasma TG levels were determined fluorimetrically using a Technicon AAII (Kessler and Lederer, 1965).

Results

Fasting plasma TG levels varied widely and there was no difference between the groups. Two hours after ingesting the test meal, both control and CND groups showed a constant and significant rise in plasma TG (Table). Although the patients with CND had lower levels than controls, they were clearly distinct from both groups with IFM and MP who showed a slight rise in plasma TG levels. Fig. 1 shows the 2-hour rise of plasma TG in each patient. None of the children with gastrointestinal disease showed a rise >40 mg/100 ml (>0·4 mmol/l). Of the 29 patients studied, 11 had no rise at all and some even had a decrease in plasma TG values. They differed significantly from controls and patients with CND who exceeded a slight rise of 55 mg/100 ml. The only exception, a 4-year-old child with recurrent diarrhoea, had also a borderline coefficient of fat absorption of 88% but no other evidence of gastrointestinal disease.

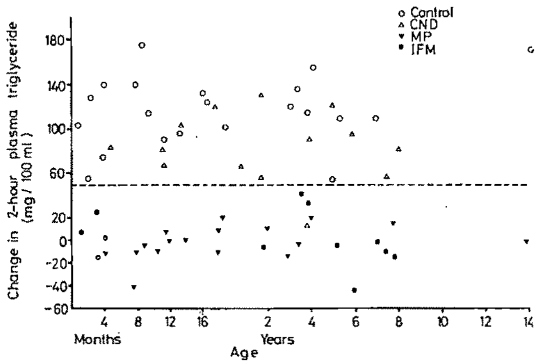

Fig. 1 *Two-hour rise in plasma triglyceride values after an oral fat load in various groups of patients. Broken line at 50 mg/100 ml separates patients with fat malabsorption from controls and those with CND.*

The 4-hour postloading TG values tended to return to preloading levels in most children and were not useful in identifying the various groups. These values are therefore not presented here.

By comparing the 2-hour plasma TG values with the CFA ones (Fig. 2), a significant correlation was obtained in controls ($R = 0{\cdot}84$ $y = -679{\cdot}21 + 8{\cdot}7 \times P < 0{\cdot}001$), CND ($R = 0{\cdot}77$ $y = -801{\cdot}1 + 9{\cdot}4 \times P < 0{\cdot}001$), and patients with IFM ($R = 0{\cdot}61$ $y = -95{\cdot}1 + 1{\cdot}3 \times P < 0{\cdot}05$). Only the MP group had a much lower plasma TG increase compared with their CFA, and accordingly no signiffcant correlation was observed ($R = 0{\cdot}47$, P = NS).

Discussion

The results of this study show that a 50 mg/100 ml (0·6 mmol/l) rise in plasma TG levels 2 hours after an oral fat load can serve as a useful screening procedure for separating children with gastrointestinal disease from controls and from children with CND. The inexpensive fluorimetric method proved adequate and gave results comparable with those using more expensive gas liquid chromatography (Fällström *et al.*, 1977). The procedure should thus be available routinely in clinical laboratories.

The good correlation between CFA and 2-hour rise of plasma TG levels in most children including normal controls, children with CND and IFM, suggest that this test is a reliable reflection of the processes of fat absorption in most conditions. Accordingly it may serve in evaluating various therapeutic measures in children with cystic fibrosis, bacterial overgrowth, and cholestasis. Patients with MP failed to show this correlation. In these conditions the greater disturbance of fat absorption in the proximal intestine is illustrated by the low 2-hour rise of plasma TG levels. The relatively higher CFA is possibly the result of some compensation brought about by absorption in distal, less involved parts of the gut. This may explain the better discriminating capacity of this test compared with

faecal fat measurement in patients with gluten entropathy (Fällström *et al.*, 1977). The test may prove useful in early evaluation of gluten challenge, notably the timing of postchallenge biopsy.

Children with CND constitute the bulk of clinical material seen in most gastrointestinal services. This group demonstrated a lower increase in plasma TG levels compared with normal subjects, yet, with a single exception, they could easily be separated from patients with gastrointestinal disease. Borderline CFA had previously been reported in some of these children (Davidson and Wasserman, 1966); the significance of this observation is still not known.

We thank Mrs Y. Goldberg for the lipid determinations, Mrs R. Sandak for secretarial help, and Mrs L. Tzifroni and Mrs M. Normand for their help in preparing and feeding the meal.

Serum cholecystokinin, basal acid secretion, and infantile pyloric stenosis

I. M. ROGERS, I. K. DRAINER, A. J. DOUGAL, J. BLACK, AND R. LOGAN

Stobhill Hospital and the Royal Hospital for Sick Children, Glasgow

SUMMARY The fasting serum cholecystokinin-like activity was measured in 21 infants with pyloric stenosis and in 13 normal controls. No significant difference was found between the two groups. The basal acid secretion was measured by continuously aspirating the previously emptied stomach for one hour. The basal gastric volume and the total and the free acidity were all greater in the pyloric group.

We have previously suggested that increased serum levels of cholecystokinin (CCK) may be responsible for the development and persistence of infantile pyloric stenosis (Rogers *et al.*, 1975). Infants with this condition would have inherited a greater than normal parietal cell mass and, consequently, would have gastric hyperacidity. CCK is released from the duodenum by acid stimulation (Meyer *et al.*, 1970) and causes pyloric muscle contraction (Fisher *et al.*, 1973). Antral distension due to pyloric hold-up would release gastrin with the likelihood of further acid secretion (Debas *et al.*, 1974), and hence a sequence of events leading to pyloric stenosis of infancy would result (Fig. 1). We measured the serum CCK-like activity from infants with pyloric stenosis and from normal control infants. The basal gastric acid secretion was also measured as far as was ethically possible.

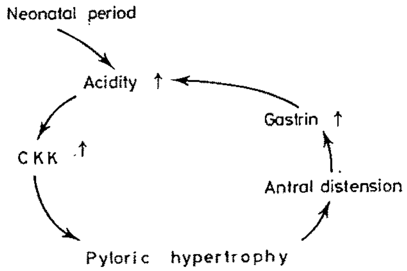

Fig. 1 *Sequence of events leading to pyloric stenosis.*

Materials and methods

21 infants with pyloric stenosis and 13 control infants were studied. The stomach was aspirated dry using a double-lumen nasogastric tube, and 3 ml peripheral blood was obtained by venepuncture. The serum was quickly separated and immediately frozen for subsequent analysis of CCK-like activity.

Serum CCK was determined by radioimmunoassay as described elsewhere (Harvey *et al.*, 1974a). The antiserum used (OC2/9) was raised against the C-terminal octapeptide of CCK (provided by Dr M. Ondetti, Squibb Institute) and used at a working dilution of 1/30 000. All samples were measured in triplicate, and samples from the paired tests in individual infants were measured in a single assay. However, as at least 3 molecular forms of CCK are present in blood and tissues (Harvey *et al.*, 1974b), and as the assay detects all 3, it was decided to categorise the CCK values into low, medium, or high range.

The gastric aspirate obtained by one hour's continuous suction was analysed for volume, pH, and free and total acidity. With the control babies the gastric analysis was performed at least 3 hours after their last feed.

This project was approved by the ethical committee of the Royal Hospital for Sick Children, Glasgow; informed parental consent was obtained in each case.

Results

Basal acid secretion. A greater volume of gastric juice was obtained from the pyloric infants. These results were highly signficant ($P<0\cdot01$) (Fig. 2).

The basal pH did not differ significantly between the two groups ($P>0\cdot1$) (Fig. 3), but the total

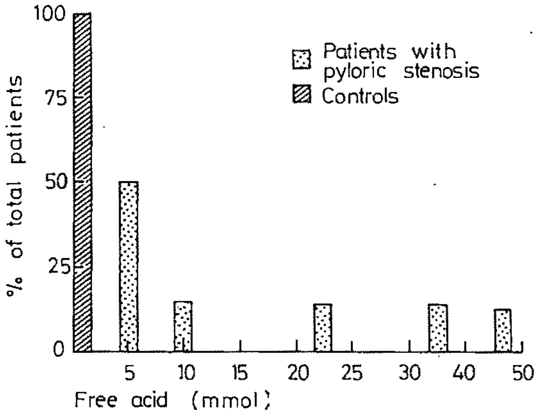

Fig. 5 *Free acidity titrated to pH* 3·5

(P<0·01) and the free acidity (P<0·05) were greater in the pyloric group (Figs 4 and 5).

None of the aspirates from the controls could be titrated to pH 3·5. This was usually because too little volume was obtained, or sometimes the starting pH was already more alkaline than pH 3·5 (Fig. 3). Hence none of these infants had measurable free acidity. Similarly in only one instance could total acidity be measured in the control group and, on that occasion, it was 19 mmol (Fig. 4).

CCK-like activity. The results obtained in both groups were generally higher than those normally found in fasted adults but due to the empirical nature of the values, this could not be verified statistically.

There was little difference in the distribution of the high, medium, or low range of CCK-like activity between the pyloric and the control group although

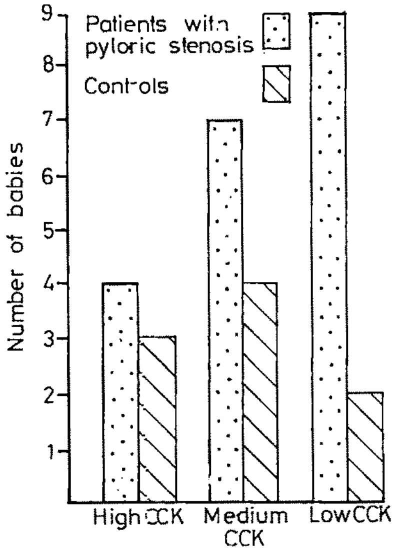

Fig. 6 *CCK-like activity.*

the pyloric group tended to accumulate more of the low range values. This tendency was not significant (Fig. 6).

In 6 infants postoperative serum samples were taken between 1 and 2 weeks after surgery. In 5 of these babies the CCK-like activity had increased to a higher range.

Discussion

The physiological basis for the development of infantile pyloric stenosis is a relatively new area of interest. It is known that the pyloric sphincter contracts *in vivo* to duodenal acidification (Fisher *et al.*, 1973) and polypeptide hormones, particularly CCK, are thought to be implicated (Isenberg and Csendes, 1972).

Our findings support the view that hyperacidity is present in infants with pyloric stenosis. This opinion presumes that no significant gastric secretion is being lost through the normal pylorus in the control infants. Our findings do not support the suggestion that increased CCK-like activity is implicated in the pathogenesis of this condition.

Our original hypothesis that hypergastrinaemia is responsible for the development and persistence of pyloric stenosis (Rogers *et al.*, 1975) has now been studied by others (Spitz and Zail, 1976; Bleicher *et al.*, 1978). Both studies confirmed the presence of hypergastrinaemia and we concede that our earlier failure to confirm hypergastrinaemia might have been due to technical considerations.

We thank M. D. Moore, biochemist, Stobhill Hospital for statistical and technical assistance, the physicians and surgeons of the Royal Hospital for Sick Children, Glasgow for allowing study of infants, and John Grant, paediatric surgeon for his encouragement and continuing interest.

Prolonged QT interval and cardiac arrhythmias in two neonates: sudden infant death syndrome in one case

D. P. SOUTHALL, W. A. ARROWSMITH, J. R. OAKLEY, G. MCENERY, R. H. ANDERSON, AND E. A. SHINEBOURNE

Cardiothoracic Institute, and Whipps' Cross Hospital, London, Doncaster Hospital, Yorkshire, and Department of Health

SUMMARY Two neonates with arrhythmias and the long QT syndrome are described. The arrhythmias were detected *in utero* and both infants were apparently well after birth. The first infant, although well, had a bradycardia for the first 9 days of life. A normal heart rate was documented at 10 days but a prolonged QT interval was not appreciated on the ECG. He was discharged from hospital but died suddenly and unexpectedly 3 days later. A post-mortem examination failed to find a cause for his death which therefore fell into the category of the sudden infant death syndrome (SIDS). A retrospective analysis of the perinatal electrocardiogram showed a probable junctional rhythm with 2:1 conduction to the ventricle; the QT interval was prolonged at 0·52 seconds (QTC = 0·63). The second infant had a QT interval of 0·52 seconds (QTC = 0·54) and frequent ventricular premature beats on a 24-hour electrocardiogram. She was treated with propranolol and remains well 2 years later. Sudden infant death has often been described in the siblings of children with the long QT syndrome and one other report described a case of SIDS which was said to have had a prolonged QT interval on the perinatal ECG. This report, however, provides unquestionable evidence, in one case, of an association between the long QT syndrome and SIDS.

Cardiac arrhythmias occur frequently in the healthy newborn infant (Morgan and Guntheroth, 1965; Southall *et al.*, 1976, 1977; Ferrer *et al.*, 1977). Some of these arrhythmias may be considered a normal finding in the newborn, but others have more serious implications as similar disorders have been reported to cause sudden death in childhood (Radford *et al.*, 1977). With other authors (Guntheroth, 1977), we have already suggested a possible link between the more serious of the arrhythmias and conduction disorders and the sudden infant death syndrome (SIDS). We describe here two apparently healthy neonates with arrhythmias and the long QT syndrome. One was treated and remains well, while the other—whose death fell into the category of SIDS—was found to have this abnormality on retrospective analysis of the electrocardiogram.

Case 1

This boy, birthweight 2·5 kg, was the first child of a 23-year old woman. She did not smoke, and her home circumstances were materially good. At 37 weeks' gestation she was admitted to hospital with moderate pre-eclamptic toxaemia and treated with frusemide 40 mg once daily, slow K 600 mg twice a day, and diazepam 5 mg three times a day. During this admission the fetal heart rate was noticed to be irregular, with slowing to less than 100 per minute. At 39 weeks' gestation spontaneous onset of labour occurred, and after 9 hours a forceps delivery was carried out for pre-eclamptic toxaemia and fetal bradycardia. The pulse rate was 140/min at birth but fell to 73/min after 12 hours. The infant was clinically well and an ECG was taken and interpreted as 2:1 atrioventricular block (Fig. 1). This brady-

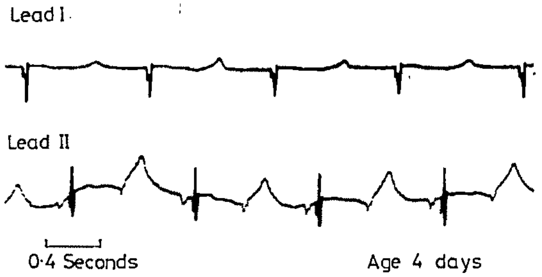

Fig. 1 *Standard ECG showing a probable junctional rhythm of 130/min with 2:1 conduction and a prolonged QT interval of 0·52 seconds (QTC = 0·63). Origin of the impulse is probably junctional rather than sinus because of the abnormal P wave axis (−90°).*

cardia persisted until 9 days of age when the heart rate reverted to 130/minute; no ECG was recorded at this time. The baby was discharged from hospital and 2 days later, while being breast fed, he collapsed and died. A post-mortem examination performed by the pathologist appointed to the Department of Health study group into SIDS failed to show an adequate cause for this death. The paediatricians who attended this infant before discharge from hospital were surprised by his death and did not consider that the transient postnatal bradycardia was responsible. A diagnosis of SIDS was therefore made by the coroner. Because of our interest in the possible association between neonatal arrhythmias and SIDS we were asked by the pathologist to review the ECG taken shortly after birth. Our interpretation was that this arrhythmia represented a probable junctional rhythm of 136/min with alternate junctional impulses failing to conduct to the ventricle because of the prolonged phase of repolarisation (a QT interval of 0·52 seconds as measured over 10 beats, QTC = 0·63). A detailed study of the conducting system of the heart was normal. The sinus node was in the expected lateral position, and was morphologically normal. The posterior atrial ganglia were related to an area of epicardial haemorrhage, but contained no inflammatory changes. The atrioventricular node was well formed, and gave rise in normal fashion to a penetrating bundle. There were slight extensions of archipelagos into the central fibrous body. The branching bundle was well formed and the bundle branches of typical morphology. No inflammatory changes were noted in the conduction tissues.

There was no family history of deafness, fainting, or sudden death, and electrocardiograms on his parents and grandparents showed normal QT intervals.

Case 2

This girl was the first child of a 22-year-old non-smoking, married woman who had emigrated to England from Pakistan 13 years previously. The mother was taking diazepam 2 mg twice daily for anxiety during pregnancy and was investigated at 28 weeks' gestation for fainting attacks. At 32 weeks' gestation a fetal bradycardia of 90/min was noticed which persisted until the time of delivery. At 39 weeks, spontaneous onset of labour occurred and a term girl weighing 2·058 kg was born. A standard electrocardiogram on the first day of life showed sinus bradycardia of 90/min and as measured over 10 beats a prolonged QT interval of 0·52 seconds (QTC = 0·54). Her serum calcium was 2·34 mmol/l (9·36 mg/100ml) and potassium 4·8 mmol/l. Subsequent electrocardiograms continued to show a long QT interval and a 24-hour electrocardiogram showed frequent ventricular premature beats (up to 40 per minute) (Fig. 2). Propranolol 1 mg 8 hourly was given and produced a pronounced reduction in the number of ventricular premature beats on the 24-hour ECG. The child is now 2 years but has a perceptive deafness. Her electrocardiogram continues to show a prolonged QT interval. She has remained well on propranolol and has never fainted. There was no family history of deafness or sudden death, and electrocardiograms on her parents have shown normal QT intervals.

Discussion

The prolonged QT interval found on the electrocardiogram in these two cases appears to represent congenital abnormalities of repolarisation. The presence of deafness in Case 2 indicates the Jervell and Lange-Nielsen syndrome (Jervell and Lange-Nielsen, 1957). Metabolic causes such as hypokalaemia, hypocalcaemia, and hypomagnaesaemia were unlikely to have been responsible for QT prolongation in Case 1 because the arrhythmia was present *in utero*.

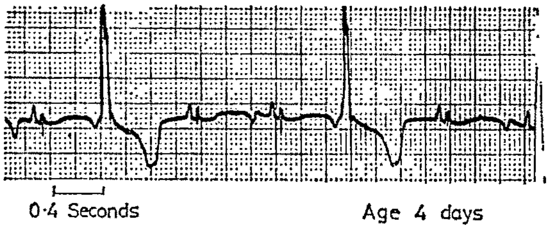

Fig. 2 *24-hour ECG showing multiple ventricular premature beats and a prolonged QT interval of 0·52 seconds (QTC = 0·54). (QRS tracings have been made darker).*

Experimental and clinical observations have suggested that the long QT syndrome may be due to a congenital disorder of the autonomic nervous system (Schwartz and Malliani, 1975; Schwartz *et al.*, 1975). While a recent study by James *et al.* (1978) demonstrated inflammatory changes in the autonomic cardiac ganglia of patients with long QT, no such changes were present in our case. It is, however, interesting to note that both mothers were taking diazepam during pregnancy. This drug is known to affect the autonomic nervous system (Dukes, 1976).

Case 1 not only had a long QT interval but also a probable accelerated junctional rhythm with 2:1 conduction to the ventricle. We suspect a junctional rather than a sinus rhythm because of the abnormal P wave axis (−90°) but an ectopic atrial focus is a possibility. We presume that alternate junctional beats failed to conduct to the ventricle because of its prolonged phase of repolarisation rather than atrioventricular node dysfunction, although we cannot exclude this latter conduction disorder. Conduction disorders probably representing sinus node dysfunction have previously been described by Olley and Fowler (1970) but to the best of our knowledge this particular arrhythmia has not been reported. An ECG was not performed when the heart rate was normal and therefore we do not know the mechanism behind this change in rate. The irregular rhythm noted before birth could have represented ventricular premature beats but none was documented on the standard ECG performed shortly after birth. In our opinion, a ventricular tachyarrhythmia associated with a low threshold for ventricular fibrillation due to the long QT interval was responsible for the sudden death of this infant, rather than asystole associated with the junctional rhythm and 2:1 atrioventricular conduction. We feel that the latter was secondary to the prolonged phase of repolarisation rather than to atrioventricular nodal dysfunction.

SIDS has been reported in siblings and other close relatives of children with the long QT syndrome (Romano *et al.*, 1963; Fraser and Froggatt, 1964; Chaudron *et al.*, 1976). Fraser and Froggatt (1964) and Schwartz (1976) suggested that some sudden unexpected infant deaths were likely to be associated with this conduction disorder. This hypothesis has however led to controversy. Maron *et al.* (1976) studied parents and siblings of cases of SIDS and found longer than normal QT intervals in some of these relatives. However, Kukolich *et al.* (1977) using similar family studies, and Kelly *et al.* (1977) in 'near-miss' SIDS cases, both failed to find significantly prolonged QT intervals. Smith (1978) has recently described a case of SIDS said to have had a prolonged QT interval of 0·32 seconds (QTC = 0·48) on a perinatal ECG but in our opinion the QT interval on the published ECG was within the normal range (Walsh, 1963). Thus Case 1 in this present study provides strong evidence to support the hypothesis that there is a causal relationship between the long QT syndrome and some cases of SIDS. As previously suggested by Schwartz (1976) and Maron *et al.* (1976), only a prospective ECG study of a large newborn population will establish the true incidence of this conduction abnormality and determine the number of sudden infant deaths associated with it.

These cases are also of interest because they were detected before birth. Ventricular fibrillation or asystole in the fetus could result in an otherwise unexplained stillbirth and it is possible that a small number of stillbirths are related to the long QT syndrome.

Despite their arrhythmias both infants were clinically well at the time of their ECGs and in our opinion it is probable that their different outcomes related to the treatment of Case 2 with propranolol. This drug has been shown to reduce the severity and frequency of syncopal episodes in the long QT syndrome (Ward, 1964; Gale *et al.*, 1970; Garza, *et al.*, 1970; Wellens *et al.*, 1972; Schwartz, 1976), possibly by reducing the incidence of ventricular tachyarrhythmias. 24-hour ECG monitoring of Case 2 showed that treatment with propranolol almost completely abolished ventricular extrasystoles.

The presence of a junctional rhythm in Case 1 might have represented an associated disorder of sinus node function. It is therefore possible that treatment with propranolol, because of its depression of automaticity and conduction (Stephen, 1966), could have precipitated dangerous bradycardias in this infant. However, a case has recently been described (Olley and Fowler, 1970), where, in this syndrome, syncope due to asystole and associated with short runs of slow junctional rhythm responded to propranolol.

The long QT syndrome is known to cause sudden death in older children. We suggest that our case of SIDS was probably due to an arrhythmia associated with this cardiac conduction abnormality. The absence of both a family history and of a prolonged QT interval in the relatives of these patients confirms that an obvious hereditary factor may not always be present. Only a large prospective study of the ECG in the newborn infant will establish the true incidence of this disorder.

We thank Dr Iain Forrest-Hay, who carried out the original post-mortem examination, for bringing Case 1 to our attention. Dr Southall is supported by a grant from the Board of Governors of the Brompton Hospital. We also thank Mrs Susan Cowley and Mrs Dorothy Lewis who typed the manuscript. The 24-hour analyser was supplied by the British Heart Foundation.

Viruses and acute abdominal pain in childhood

C. R. PULLAN, P. C. HALSE, D. G. SIMS, F. W. ALEXANDER, P. S. GARDNER, AND A. A. CODD

Department of Child Health and Public Health Laboratory, Newcastle General Hospital, and Department of Virology, Royal Victoria Infirmary, Newcastle upon Tyne

SUMMARY Children aged at least 4 years admitted to hospital with acute abdominal pain, excluding appendicitis, were investigated for the presence of viruses. Out of 181 children 29 were found with viruses of whom 18 had nonspecific abdominal pain. Eight others were found to have virus-like particles on electron microscopical examination of their faeces. Virus infections contribute to a small extent to nonspecific abdominal pain in childhood, but in many cases the cause remains unknown.

In any series of children with acute attacks of abdominal pain worrying enough to require admission to hospital, there is a large proportion (30% in Jones, 1976; 36% in Sims and Alexander, 1976), in which no cause for the pain is identified. In some of the remaining cases it is possible to demonstrate the presence of a respiratory virus infection.

Kerr *et al.* (1975) looked at two epidemics of influenza B in Newcastle and found that a high proportion (41%) of those aged at least 4 years had abdominal pain as a major symptom. Children admitted to this hospital with abdominal pain in 1973 and 1974 were studied retrospectively, identifying some with positive virology (Sims and Alexander, 1976). We decided to look prospectively at admissions of children with acute attacks of abdominal pain to try to ascertain (1) which viruses could be demonstrated, and (2) whether these viruses affected particularly those with unexplained abdominal pain and fever.

Method

Children aged at least 4 years were entered into the study if they were admitted as an emergency complaining of acute abdominal pain between mid-July 1975 and the end of April 1977. Those with acute appendicitis were excluded.

On admission the children had the following investigations: (1) Nasopharyngeal secretions (NPS) for viral diagnosis by the flourescent antibody technique (FAT) and by culture. (2) Nose and throat swabs for viral culture. (3) Stool for viral culture and electron microscopy (EM). (4) Serum for viral antibody titres by complement fixation. Blood samples 10 days later were repeated if possible. (5) Blood for a white cell count and differential. (6) Urine for culture and microscopy. (7) Throat swabs for bacterial culture.

Results

During the 21½ months of the study, there were 297 admissions with acute abdominal pain and 85 (29%) of these had appendicitis. 181 (85%) of the remaining 212 had some virological screening and were studied further. Most of those who had no specimens taken were admitted and discharged over a weekend. 80 (44%) of the detailed study group were boys and 101 (56%) were girls. Their ages ranged from 4 to 16 years. 123 (68%) had had pain for 2 days or less, and only 22 (12%) had had pain for over 4 days. 37 (20%) had abdominal pain only; 84 (46%) had associated vomiting. 49 (27%) had fever ≥38°C during their admission. There was no clustering of cases or seasonal variation.

The diagnoses are listed in Table 1. Children diagnosed as having nonspecific abdominal pain had acute pain, without any apparent cause, associated sometimes with vomiting and generally lasting for 1–2 days before settling. Those diagnosed as having recurrent abdominal pain had an acute

episode of pain with a history of a number of similar previous episodes where no cause had been found.

Investigations are listed in Table 2.

We identified 33 viruses in 29 (16%) cases, 18 of whom had nonspecific abdominal pain (Table 3). Virus-like particles were seen on electron microscopical examination in the faeces of 8 additional children. Four had spherical particles of 19–22 nm with well defined capsids and generally showing hollow forms (Fig. 1). Three had spherical particles of 28–31 nm with well defined capsids, capsomeres

were very small, and hollow forms were absent (Fig. 2). In one child, both types of particles were seen; 5 of these 8 children had nonspecific pain, 2 had recurrent pain, and one had associated upper respiratory tract symptoms.

Seven (4%) of the children had a group A β-haemolytic streptococcus grown from the throat swab. Five of these had symptoms of an upper respiratory infection; one had a urinary infection; one had nonspecific abdominal pain and echo 30 in his upper respiratory tract.

31 (17%) of patients had neutrophil counts of at least $8 \cdot 0 \times 10^9/l$, and of these, 3 had urinary tract infections and 2 pneumonia. Only 8 had a lymphopenia of $1 \cdot 5 \times 10^9/l$ or less. There was no correlation between the white cell count and the presence of a virus.

A fever of 38°C or above was found in 49 (27%). Of those children with nonspecific abdominal pain, fever was found more often in those in whom a virus was present (6 of 18) than in those in whom a virus was not found (12 of 81). The numbers are small and there is no statistical significance ($P<0 \cdot 1$).

Discussion

Viral infection in childhood seems to play only a small part in the production of abdominal pain.

Viruses are found in asymptomatic children, particularly in faeces (Gamble, 1962; Galbraith, 1965), but also in the upper respiratory tract (Poole and Tobin, 1973; Horn and Yealland, 1974). The present series was not controlled because of the difficulty in obtaining appropriate controls matched for age and season. One would perhaps expect to find a virus in children with symptoms of upper respiratory tract infection, gastroenteritis, or in certain cases of meningitis. Abdominal pain associated with upper respiratory tract symptoms is often called mesenteric adenitis and presumed to be viral.

It is the group with nonspecific pain which is particularly interesting. We found a virus in 18 of 99 children with this diagnosis.

There was not a particularly large epidemic of influenza A or B during the study period or we might well have found a more striking relationship with these viruses. Kerr *et al.* (1975) noted that there had been an increase in the number of admissions with abdominal pain during the influenza B epidemics of 1973 and 1974.

An increasing number and variety of virus particles is being found in faeces by electron microscopical studies, and some unidentifiable virus-like particles were found in the faeces of the study children. Until more is known about the incidence of these particles in asymptomatic people their significance will remain in doubt.

Current topics

The diagnosis of coeliac disease

A commentary on the current practices of members of the European Society for Paediatric Gastroenterology and Nutrition (ESPGAN)

A. S. MCNEISH, H. K. HARMS, J. REY, D. H. SHMERLING, J. K. VISAKORPI, AND J. A. WALKER-SMITH

University of Leicester, Leicester, Universitäts-Kinderklinik, Munich, Hôpital des Enfants Malades, Paris, Kinderspital, Zurich, University of Tampere, Finland, and Queen Elizabeth Hospital for Children, London

SUMMARY In 1977, 53 members of ESPGAN completed a questionnaire on their current practice in diagnosing coeliac disease. The usefulness of the 'Interlaken' criteria enumerated 9 years previously was reassessed. Details were obtained about the initial diagnostic approach, the acceptable histological criteria of the initial jejunal biopsy, and the timing, technique, response, and interpretation of early and late rechallenges with gluten.

Answers indicated that, although the initial mucosal lesion is usually 'flat' at the time of diagnosis, a few infants may present at a time when the mucosal lesion is less completely damaged. Furthermore, the degree of histological change after gluten challenge that is acceptable as a positive response may vary according to the state of the mucosa before challenge.

It was noted that there are still no generally agreed criteria by which the histological lesions may be described, so that (after further discussions at the Third International Coeliac Conference in Galway) a European panel has been set up to make recommendations.

In the experience of ESPGAN members, most coeliac children will have a histological relapse within 2 years of reintroduction of gluten. But a small number of unorthodox cases were reported that suggest that (a) histological relapse may take longer than 2 years to appear, or (b) the degree of sensitivity to gluten may vary at different ages.

Very long-term follow-up will be needed to explain these anomalies. Meanwhile the search continues for 'the basic defect'.

In 1969, members of the (then) European Society of Paediatric Gastroenterology discussed in Interlaken the criteria for diagnosing coeliac disease. Their conclusions were published (Meeuwisse, 1970) and contained the following points: (1) Coeliac disease is a permanent condition of gluten intolerance. (2) The initial mucosal lesion is 'flat', and recovers on a gluten-free diet. (3) Reintroduction of gluten will produce a histological relapse within 2 years.

These points were subsequently described as criteria for the definitive diagnosis of coeliac disease in childhood (Visakorpi, 1974).

It was also noted in Interlaken that transient gluten intolerance, if it exists, is rare, and that more facts are needed.

Nine years after the original discussion, 53 members of the (now) European Society for Paediatric Gastroenterology and Nutrition (ESPGAN) completed a questionnaire on their current practice in diagnosing coeliac disease. The questions were designed to find out how often and in what manner 'the Interlaken criteria' were used.

J. A. WALKER-SMITH, consultant paediatrician

Details were obtained about the initial diagnostic approach to a child with suspected coeliac disease; the most commonly used laboratory tests; the acceptable histological criteria of the initial biopsy; and the timing, technique, response, and interpretation of early and late rechallenges with gluten. The results were discussed at the annual meeting in Utrecht in 1977, and some of the basic data have been presented elsewhere (Shmerling, 1978).

We believe that this questionnaire and the ESPGAN discussion that followed have given important information to test the validity and usefulness of 'the Interlaken criteria' and have raised new problems in the diagnosis of coeliac disease. We met in Zurich in September 1978 to examine further the results of the questionnaire and the discussion that took place in Utrecht. The following paragraphs are our commentary, based on the current thinking and practice of the members of ESPGAN.

Initial mucosal lesion

A 'flat' mucosa with absent or nearly absent villi has been widely accepted as an essential diagnostic feature of coeliac disease in childhood (Visakorpi, 1974). The discussions in Utrecht showed that this continues to be the usual finding in untreated childhood coeliac disease. However, it now appears certain that, in a few cases (which have been confirmed later by positive gluten challenge), the initial mucosal lesion is not 'flat' but is 'severely damaged' (Walker-Smith *et al.*, 1978). This less extreme lesion has been found in young infants and is likely to be the result of a relatively low gluten intake, ingested over a relatively short period. Great caution must be shown before diagnosing coeliac disease in such infants with less severe mucosal lesions, because there are other conditions that can cause similar histological changes. If the condition of the child permits, it may be possible to continue a diet containing a known (adequate) amount of gluten for a few weeks before repeating the biopsy. Whether or not this practice is adopted in individual cases, all must be rechallenged later (see below) for final proof of the diagnosis.

During these and subsequent discussions (at the Third International Coeliac Conference in Galway) it became clear that there are still no generally agreed criteria by which the histological lesions may be described. A European panel has been set up to make recommendations.

Gluten challenge

It is a central part of the definition of coeliac disease that the disease is permanent. The implication that follows is that reintroduction of gluten into the diet (a gluten 'challenge') will produce a relapse.

In the original Interlaken paper, it was stated that 'the only decisive criteria are the abnormal morphology of the small intestinal mucosa, its normalisation on gluten withdrawal, and the reaction on reintroduction of gluten.' It was also stated that the mucosa should be normal before rechallenge.

In 1977, the only significant change in these views related to the state of the mucosa before attempting rechallenge, and to the degree of mucosal change that is induced by the challenge. About 14% of members now consider that it is not necessary for the mucosa to be completely normal before attempting challenge; in such cases the reappearance of severe lesions would be necessary before deciding that the challenge was 'positive'. About the same proportion of members felt that, if the mucosa before challenge was normal, then a 'deterioration' of mucosal histology could be considered evidence of a positive response.

There is obvious need for caution in this approach, otherwise coeliac disease will be wrongly diagnosed and its frequency will be overestimated. A further difficulty at present is our inability to define precisely the degree of mucosal change. This is another area where it is hoped that the European panel will be able to introduce more satisfactory criteria.

Transient (temporary) gluten intolerance and 'the 2-year rule'

At Interlaken, the panel and most of the audience agreed that transient gluten intolerance (if it exists) is relatively rare. It was further stated that 'before a patient is classified as having been suffering from transient gluten intolerance the intestinal biopsy should still be normal 2 years after the reintroduction of gluten'.

In Utrecht, there was general agreement that the condition does exist, that it usually occurs in young infants, and lasts 'for a short period'—generally a few weeks or months. The pathogenesis may be similar to that in cows' milk protein intolerance. There are no firm data on the upper age limit or maximum duration of transient gluten intolerance. Stricter criteria, including a positive early challenge and a negative late challenge have been described elsewhere (McNeish *et al.*, 1976), but they are difficult to apply routinely. It should be noted that a positive early challenge will be found in both transient intolerance and coeliac disease, and that a late challenge will be required to confirm either diagnosis.

The '2-year rule' was originally developed in the context of temporary gluten intolerance (see above), but it carried the implication that, in cases of permanent gluten intolerance (that is, coeliac disease), there would be a recurrence of the mucosal lesion within 2 years of gluten reintroduction. Discussions at Utrecht confirmed that this concept had proved useful, and that most coeliac children who have been challenged have obeyed it. ESPGAN members have performed challenges on 652 children, and 619 (95%) have shown mucosal relapse within 2 years. Those who did not relapse within 2 years may represent a heterogeneous population, since the cases were studied in different centres at different ages, and with no uniformity of approach to the method of gluten challenge. They comprise at least two groups. In the first, there was no relapse after gluten reintroduction, and these children may have had transient gluten intolerance that had recovered spontaneously. In the second group, 7 members reported 20 patients in whom there was a histological relapse after 2½ to 7 years. Precise information is available on only 7 of these children, and still more thorough analysis of their data is needed and is being sought. If these claims are substantiated, they may alter recommended clinical practice.

Permanence of coeliac disease and gluten challenge

This key concept appears to have been accepted in principle. The implication that follows is that gluten challenge will always produce a relapse. While the answers to the questionnaire indicated virtual unanimity of belief on this point, there remains a considerable discrepancy in clinical practice. Some members thought that the place for gluten challenges was in research clinics only, and did not challenge their patients; others did not routinely challenge patients in whom early diagnostic features and responses to a gluten-free diet were 'classical'; still others challenged only those infants in whom the initial diagnoses were made at less than one year, in the belief that it is in this age group that there might be confusion between coeliac disease and transient gluten intolerance.

The gap that exists between theory and practice is illustrated by the fact that only 652 gluten challenges have been performed in clinics that must contain several thousand 'coeliac' children.

Conclusions and some questions for the future

The 1969 Interlaken statement concluded: 'these results do not solve the problem of diagnostic criteria of coeliac disease, and do not impart to us the "final truth" about the disease'. Nearly a decade later, the 'final truth' still eludes us, but we think that the original criteria have served us well, and at present do not need to be changed. The basic data from the 1977 questionnaire (Shmerling, 1978) indicate a considerable degree of uniformity of thinking, and the Interlaken statement has clearly been influential.

Some workers have a less rigid approach than formerly to the minimum diagnostic histological criteria of the initial biopsy. There is obvious need for caution in this approach, otherwise coeliac disease will be wrongly diagnosed and overdiagnosed. It is hoped that the European panel will be able to define the histological lesions more satisfactorily.

The need for gluten challenge is widely recognised but is less widely practised. Research workers will rightly continue to say that all coeliac patients should have confirmatory gluten challenge. But first, more satisfactory criteria for a positive challenge are needed, and this itself requires more research. For the practising clinicians who at present choose not to challenge every patient, there are no definite rules about whom they should select for challenge. Some recommend for challenge all those in whom the original diagnosis of coeliac disease was made before age one year, and those in whom the original features or therapeutic response was not 'classical'. Of course this begs the question.

When the '2-year rule' is applied, some unanswered problems arise that will only be resolved by very long-term follow-up. A positive gluten challenge is used to indicate *permanence* of the intolerance, whereas it only proves *persistence* of the abnormality. Furthermore, it is possible that clinical (and possibly histological) 'expressivity' of the disease, including the degree of gluten sensitivity, may vary at different ages. Three cases (Schmitz *et al.*, 1978) have already been reported in whom a positive gluten challenge was later followed by apparent gluten tolerance, as indicated by spontaneous remission of the small intestinal mucosal lesion on a gluten-containing diet. These cases were older and the period of gluten intolerance was much longer than cases of 'transient' intolerance.

The 7 (or more) cases in whom the mucosal lesion took longer than 2 years to relapse after gluten reintroduction require more detailed documentation. If the claims are substantiated they may alter recommended clinical practice, if not basic pathophysiological concepts.

Lastly, what should be the management of the child whose original features and histology suggest coeliac disease, who apparently recovers on a gluten-free diet, but in whom no adverse response to gluten occurs after 2 years of reintroduction? Some, perhaps the majority, will rightly be considered to have had 'transient' intolerance which is now cured, and will be discharged from the clinic. The coeliac research worker will consider all the above discussions, and may decide upon very long-term follow-up to exclude late relapses.

Meanwhile the search continues *in vitro* (Katz and Falchuk, 1978) and *in vivo* for 'the basic coeliac defect'. The answers to some of the clinical problems discussed above may have to await this dénouement.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onwards all manuscripts submitted should accord with the new style.

Short reports

Caffeine secretion into breast milk

EILEEN E. TYRALA AND W. EDWIN DODSON

Edward Mallinckrodt Department of Pediatrics and Department of Neurology and Neurological Surgery (Neurology), Washington University School of Medicine, and the Divisions of Neonatology and Pediatric Neurology, St Louis Children's Hospital, Missouri, USA

SUMMARY Serum and milk concentrations of caffeine were measured in 5 breast-feeding mothers after a standardised oral dose of caffeine. Peak concentrations of caffeine in serum and milk were attained 60 minutes later. Binding of caffeine by constituents of serum and breast milk was low (25 and 3·2% respectively). In breast milk, caffeine binding is associated with the cream layer, and correlates with the butter fat content. Caffeine does not diffuse freely into breast milk and concentrations in milk are lower than in maternal serum.

Most breast-feeding mothers will ingest daily some quantity of caffeine from coffee, tea, or soft drinks. Information about the passage of caffeine from serum into breast milk, however, is limited (Illingworth, 1953). We studied the relationship between serum and milk concentrations of caffeine after the ingestion of a standardised oral dose.

Subjects

Five healthy white women participated in the study. The subjects ranged in ages from 25 to 31 years, weighed 53·1 to 70 kg, and had been nursing their infants for periods of 4 months to one year. The purpose and procedure of the study was explained to each woman and her informed consent obtained. Each was asked to refrain from taking any coffee, tea, or soft drinks in the 24-hour period immediately before the study.

Methods

All studies were done approximately 2 hours after a morning meal. 150 or 300 mg caffeine in the form of caffeine sodium benzoate diluted with approximately 2 oz (60 ml) water was taken by each woman within a 3-min period. Blood and milk were collected at time 0 and at 30, 60, and 120 minutes after taking the caffieine.

The caffeine concentrations in serum and breast milk were measured by gas liquid chromatography. 250 μl milk and 100 μl serum were pipetted into 12 ml conical tubes into which etidocaine, the internal standard, had previously been pipetted and dried. Samples were capped and stored at −20°C until analysis. Extraction was carried out by adding 5 ml isopropyl alcohol and chloroform (5:95) to each specimen, mixing for 30 seconds with a Vortex mixer, freezing the aqueous layer by immersion of the tube in a dry ice and acetone bath, and decanting the organic layer. The extraction was repeated, and the organic phases pooled and dried under nitrogen. Each dried extract was redissolved in 50 μl chloroform and 2 μl was injected into the gas chromatograph. A Hewlett-Packard 5830A gas chromatograph was equipped with a flame ionisation detector and a 1·8 m glass column packed with 3% SE–30 on 100–120 Gas Chrom. Q (Applied Science). The initial oven temperature of 195°C was kept for 2½ minutes and then it was increased at a rate of 2°/min. Injector temperature was 250°C, and the detector temperature 300°C. Nitrogen flow was 35 ml/min. Retention time of caffeine and etidocaine were 3·44 and 6·8 minutes respectively. Peak height ratios were calculated and compared with drug supplemented standards processed identically for determination of concentrations of caffeine in the samples of milk and serum.

Protein binding of caffeine in milk and serum was determined by equilibrium dialysis. 10 μl ^{14}C-labelled caffeine (40–60 mCi/mmol) (New England Nuclear) was added to 1 ml samples of milk and serum which then were dialysed against 1 ml 0·2 mol/l phosphate buffer, saline solution, pH 7·4 at an osmolality of 290 mmol. After incubation at 27°C for 5 hours, radioactivity was counted in duplicate aliquots of sample and dialysate. The fraction of unbound drug was calculated by dividing the radioactivity in the dialysate by the radioactivity in the sample. Binding of caffeine in skimmed breast milk and cream was studied by adding radioactive caffeine to whole milk, separating the layers by centrifugation, and performing equilibrium dialysis on both the skimmed milk and cream layers as described above. Butter fat content of the milk was determined by Pevely Dairy Company, St Louis, Missouri.

Results

The Table summarises the data obtained from the 5 women. After the ingestion of 150 mg caffeine, peak concentrations of caffeine in serum ranged from 2·39 to 4·05 μg/ml, and peak concentrations in milk ranged from 1·4 to 2·4 μg/ml by 60 minutes. Doubling the dose of caffeine to 300 mg resulted in a doubling of the serum caffeine concentration at 30 and 60 minutes and did not alter the milk to serum concentration ratio in the one woman studied. At all time intervals the caffeine concentration in milk correlated with that in serum ($0 \geq 30$ min, $r = 0{\cdot}93$; $30 \geq 60$ min, $r = 0{\cdot}80$; $60 \geq 120$ min, $r = 0{\cdot}90$). For each time interval, the correlation coefficient (r) between the concentrations in serum and milk was 0·89. Analysis by linear regression indicated a linear relationship between serum (x) and milk (y) caffeine concentrations with an intercept (b) of 0·342 and slope (a) of 0·381 ($y = ax + b$).

Caffeine appeared to equilibrate rapidly between serum and breast milk. No caffeine was detected in baseline samples of milk or serum. The average of the milk to serum concentration ratios was 0·52 (SD 0·098). The ratios were derived from comparisons of the areas under the paired concentration versus time curves (milk divided by serum) and provide a measure of average concentration ratios over time. The one-way analysis of variance was used to test the possibility that the milk to serum concentration ratio varied significantly at each time interval. No significant differences were found ($F = 0{\cdot}972$; $v_1 = 2, v_2 = 12$).

The average binding of caffeine to constituents of serum and whole breast milk was 25·1% (SD 2·97) and 3·2% (SD 2·04) respectively. After centrifugation of the breast milk, all of the binding was accounted for by the creamy layer, no binding being detected in the skimmed breast milk. The butter fat content of the milk correlated with caffeine binding ($r = 0{\cdot}62$). Analysis of the relationship of the fat content of milk (x) to the percentage of caffeine bound in milk (y) by linear regression indicated an intercept (b) of 0·22 and a slope (a) of 1·47. The fat content of the five samples ranged from 1·8 to 6·1%. An average of 4·2% (SD 2·4) of the caffeine in cream was nondialysable, a percentage which agrees well with the 3·2% binding determined in whole breast milk.

Discussion

After the newborn period, nursing infants are likely to ingest caffeine in breast milk. Caffeine, a methyl xanthine present in coffee, tea, and soft drinks (Abramowicz, 1977), is a neurological and myocardial stimulant and may cause coronary artery dilatation, smooth muscle relaxation, skeletal muscle contraction, or diuresis (Ritchie, 1975).

The administration of 2·5 to 5 mg/kg caffeine to preterm infants once or twice daily after a loading dose of 10 mg/kg produces a significant decrease in apnoeic spells (Aranda *et al.*, 1977). There is little information however, about other specific effects, or about the toxicity of caffeine in infants. One 12-month-old child who took between 1 and 1·5 g developed agitation, hyperglycaemia, hypertension, tachycardia, haematemesis, and diuresis (Sullivan, 1977).

Newborn infants eliminate caffeine more slowly than adults and could develop high concentrations if comparable amounts were taken regularly. The half-life of transplacentally acquired caffeine in term newborn babies averaged 80 hours (Parsons *et al.*, 1976) (SD 26 hours). For preterm infants, caffeine elimination is even slower; an average half-life of 97·5 hours was reported in one study (Aranda *et al.*, 1977). Both of these values for half-life are much longer than the average of 3·5 hours reported for adults (Parsons *et al.*, 1976). The average half-life of caffeine for infants after the newborn period is unknown. If caffeine intake was sizeable and if caffeine half-life was comparable with the values found for newborn infants, toxic concentrations might accumulate in infants of nursing mothers with large caffeine intakes.

Our studies show that although caffeine rapidly enters breast milk, the concentrations in milk are less than expected at equilibrium after diffusion. If caffeine diffused freely from serum to milk, caffeine binding to milk and serum constituents should determine the distribution ratio. Considering that 75% of serum caffeine was unbound and available for diffusion into milk, the predicted milk to serum concentration ratio is 0·78*. The lower ratio (0·52) we observed could indicate either that the caffeine-equilibrated milk was diluted by one-third with milk secreted before caffeine dosage, or that some additional barrier reduces the diffusion of caffeine into milk. If the former were true, at later times the ratio of caffeine concentrations in milk versus serum should have increased as the dilution effect was reduced. We tested this possibility, and the differences in the average ratios at different times were insignificant, indicating no evidence of dilution. We conclude that the data indicate that the diffusion of caffeine from serum into milk is influenced by factors other than the degree of protein binding.

The property of reduced binding of caffeine by constituents of milk relative to those in serum may be an additional factor influencing drug concentration in milk. Decreased binding in milk relative to serum has been demonstrated for the related methyl xanthines, theophylline (Yurchak and Jusko, 1976), and theobromine (Resman *et al.*, 1977). This would tend to reduce the chances of an infant ingesting toxic amounts of these and other drugs that behave in a similar manner.

Can an infant acquire a significant concentration of caffeine by nursing? Our studies indicate that the nursing infant would receive only a low dose of caffeine after the mother drank a single cup of coffee (150 mg caffeine). A litre of breast milk collected during the first hour after the mother's dose would contain approximately 1·5 mg caffeine. With repeated maternal caffeine ingestion, the caffeine accumulated in the infant would depend on the average concentration in maternal serum and breast milk over time, the volume of milk ingested, and particularly, the infant's clearance rate for caffeine. If older infants have prolonged caffeine elimination rates comparable with newborns, they might accumulate significant amounts of caffeine, although the concentration of caffeine in breast milk is relatively low. Additional studies among infants nursing from mothers who routinely ingest more caffeine than we gave, and studies of caffeine clearance in older infants, are necessary to answer the question.

*If the unbound fractions diffuse freely and are in equilibrium, and if the concentration in serum is unity, the expected ratio of concentrations in milk versus serum is calculated (0·75 (unbound in milk) + 0·03 (bound in milk) ÷ 0·75 (unbound in serum) + 0·25 (bound in serum)) = 0·78.

Recurrent osteolytic lesions and subcutaneous fat necrosis in association with a developmental pancreatic cyst

P. HOLLINGWORTH, D. ISAACS, AND G. BYDDER

Northwick Park Hospital and Clinical Research Centre, Harrow, Middlesex

SUMMARY A girl had repeated episodes of widespread osteolysis, subcutaneous fat necrosis, and periarticular fat necrosis mimicking arthritis. Her symptoms persisted for 4 years, after an initial episode of severe abdominal pain, and were accompanied by only minor abdominal symptoms. She was found to have a developmental pancreatic cyst (which was excised).

Disseminated fat necrosis is a rare complication of acute or chronic pancreatitis and pancreatic pseudocysts. It is usually an isolated rather than a recurrent event. This report describes a child with repeated osteolytic lesions, occurring over a 4-year period, in whom the diagnosis was ultimately made of a developmental pancreatic cyst.

Case report

A 7-year-old English girl was referred to this hospital in January 1977 with painful swollen fingers and toes. She had presented elsewhere shortly before her 5th birthday with swelling of the dorsum of the right foot. This had settled on antibiotics after drainage of a large amount of pus, but no organism had been isolated. One week later she had developed severe abdominal pain and fever, and at laparotomy free pus was present. This had again been sterile and no cause was found. A diagnosis of primary peritonitis had been made, antibiotics were continued, and she made a complete recovery.

After a further 3 months she had developed painful swelling of the dorsum of the left hand and of 2 toes on the left foot, with intermittent pyrexia. WBC was 22×10^9/l, predominantly neutrophils but with an eosinophilia of $1\cdot7 \times 10^9$/l. Antibiotics had been given and the lesions resolved. Three weeks later she had developed a painless, hot swelling of the thigh which became fluctuant. 1 ml of sterile fluid was aspirated. Immune deficiency was suspected but full investigations did not support this.

One year later, after a bout of diarrhoea, she had further pain and swelling of 2 toes and the terminal phalanges of all fingers of the right hand, and was referred to this hospital. On direct questioning it was found that all previous episodes had been accompanied by loose stools and she had had occasional bouts of abdominal pain, although these were not sufficiently severe for her to see a doctor.

X-rays of the affected areas showed lytic lesions breaching the cortex but without periostitis. The differential diagnosis initially was felt to be between leukaemia, sickle cell disease, histiocytosis X, multiple septic emboli, and other causes of osteolysis. Blood film showed no anaemia, no leucocytosis, and no abnormal cells, but slight eosinophilia. Haemoglobin electrophoresis was normal, as were neutrophil function tests. Antibiotics were withheld and the pain and swelling settled over a few weeks, with considerable recalcification radiologically (Fig. 1).

The girl remained well for a year, during which time she failed to attend follow-up appointments. She then presented, again after a bout of diarrhoea, with swelling of the hands and feet settling without

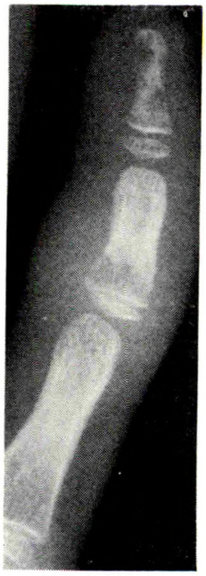

Fig. 1 *Osteolytic lesions of the 5th finger January 1977. (12 months later x-ray showed disappearance of the lesions).*

treatment. Two weeks later she was admitted with swelling of one of the labia majora and subsequent panniculitis of the adjoining part of the thigh. A mass palpable in the left hypochondrium was thought to be the spleen. However barium meal showed a soft tissue mass in the region of the left kidney. Intravenous pyelogram and anterior ultrasound examination were both normal, but a CAT scan showed a cyst near the tail of the pancreas (Fig. 2). Serum amylase was >2000 Somogyi units/100 ml (normal <200 units/100 ml). There was no history of abdominal trauma nor was there any suspicion of non-accidental injury.

At laparotomy the pancreas appeared normal. A 6 cm cyst lay between the colon and the pancreas but separate from both. This was excised. Histology showed a cyst made of a fibrous wall, lined by mucous columnar cells. Within the wall were glands lined by mucous columnar cells, goblet cells, columnar cells with a brush border, and Paneth's cells. In addition, the wall contained pancreatic acini and islets of Langerhans. The appearances were of a pancreatic developmental cyst incorporating both intestinal and pancreatic tissue. Subsequently the patient has remained symptom-free.

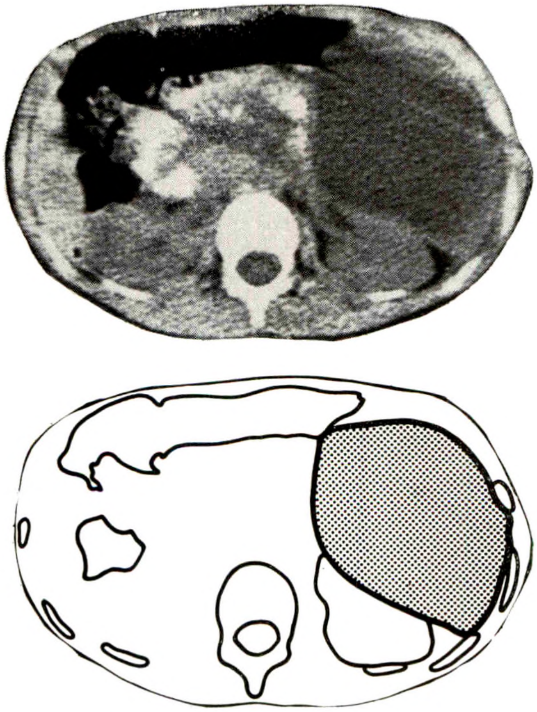

Fig. 2 *CAT scan of the abdomen. Position and extent of cyst are shown in diagram.*

Discussion

Although fat necrosis associated with pancreatic disease is usually intra-abdominal, disseminated fat necrosis may occur in the subcutaneous, periarticular, bone marrow or visceral fat. This is caused by pancreatic enzymes released into the circulation, and osteolysis may be secondary to necrosis of bone marrow or due to damage of small vessels by lipase (Achord and Gerle, 1966). Osteolytic lesions may be multiple and silent, but tend to be painful when affecting the small bones of the hands and feet. In children *x*-rays show punched-out lesions, sometimes with breach of the cortex and overlying periostitis, and radiological resolution may take months. The lesions are similar to the osteolytic lesions of metastatic neoplastic disease, sickle cell disease, and haematogenous osteomyelitis.

Subcutaneous fat necrosis presents as tender nodules while necrosis of periarticular fat may mimic arthritis. Fever, leucocytosis, and eosinophilia are common. Disseminated fat necrosis is a recognised complication of acute or chronic pancreatitis and pancreatic pseudocysts. When following acute pancreatitis the lesions may appear some weeks after apparent recovery (Shackleford, 1977).

Pancreatitis in childhood is being recognised with increasing frequency. Trauma is the most common cause, particularly handlebar injury, but child abuse should be excluded. Drugs, particularly corticosteroids and thiazide diuretics, may be responsible, and pancreatitis may be associated with mumps in which case it is invariably slight.

Pancreatic pseudocysts can follow acute pancreatitis and in most cases trauma has been implicated or suspected (Moossa, 1974). The child commonly presents some days or weeks after the injury with repeated vomiting or an 'acute abdomen'. A true cyst of the pancreas is said to be histologically distinguishable from a pseudocyst by the presence of an epithelial lining, but in practice the distinction is often difficult. True cysts are much less common than pseudocysts and may be neoplastic, hydatid, or congenital. Congenital cysts may be associated with mucoviscidosis or polycystic kidneys, or they may be developmental. The last are exceedingly rare (Miles, 1959), the few reported cases have presented with abdominal pain or swelling. In the case reported here the relationship between the patient's abdominal pain and her symptoms from disseminated fat necrosis was obscure. Measurement of serum amylase might have enabled the diagnosis to have been made earlier.

We thank Lord Smith of Marlow, Dr S. M. Tucker, and Dr B. M. Ansell for permission to report this patient.

Lumbar punctures, meningitis, and persisting pleocytosis

KEVIN D. CONNOLLY

Children's Research Centre, Our Lady's Hospital for Sick Children, Dublin

SUMMARY A retrospective survey of children with haemophilus and pneumococcal meningitis was carried out to assess the significance of persistent CSF pleocytosis and the need for repeat lumbar punctures after adequate treatment. Persistent pleocytosis was noted in 9 of 27 patients with haemophilus meningitis; this tended to be present in those with higher initial CSF white blood counts and lower initial CSF glucose contents. No sequelae were noted in those with persistent pleocytosis. Repeat lumbar punctures were not of clinical benefit and tended to result in longer treatment which was not warranted.

One criterion used to decide when to stop treatment in a child with bacterial meningitis is the presence of a CSF white blood count of $<0{\cdot}050 \times 10^9$/l after 10–14 days of treatment (Smith *et al.*, 1973). However, not only may a lumbar puncture be dangerous (Shinefield, 1975), but children who have received apparently adequate treatment can show persistent increases in the CSF white blood count. This survey was carried out to assess the significance of persistent pleocytosis and the need for a repeat lumbar puncture in a clinically well child after reasonable treatment.

Patients and methods

Records of all patients aged over 2 months admitted to this hospital between January 1972 and July 1977 with a diagnosis of bacterial meningitis were examined. The survey was confined to those who grew *Haemophilus influenzae* or *Streptococcus pneumoniae* from their CSF. Patients with recognised anatomical defects of skull or spine, those with immunological disorders, and those who did not have lumbar punctures repeated between days 10 and 14 were excluded. Those with meningococcal meningitis were also excluded as very few have persistent pleocytosis and their prognosis is better.

All those with *H. influenzae* received chloramphenicol for at least 10 days. In addition 22 received ampicillin for 10 days. 13 were given sulphonamide and 5 were given penicillin for varying periods. All with pneumococcal meningitis received penicillin for at least 10 days. In addition, 6 were given chloramphenicol, 6 were given sulphonamide, and 4 were given ampicillin for varying periods. Persistent pleocytosis was defined as a CSF white blood count $>0{\cdot}050 \times 10^9$/l between days 10 and 14.

37 babies fulfilling these criteria were examined with regard to organism, initial and repeat CSF findings, duration of pyrexia, and sequelae. The duration of follow-up was from 1½ to 5½ years. Full physical and neurological examination and clinical assessment of hearing were carried out when the patients were recalled.

Results

Of the 37 patients studied, *H. influenzae* was isolated from 27, and *S. pneumoniae* from 10. Nine of the 37 had persistent pleocytosis and all of these grew *H. influenzae*. The initial CSF white blood counts in those with persistent pleocytosis tended to be higher if one excludes one baby with pneumococcal meningitis whose initial count was $64{\cdot}0 \times 10^9$/l (Table). This patient's CSF cell count fell to

Table *Comparison between patients with and without pleocytosis*

	With pleocytosis	*Without pleocytosis*
Number	9	28
Initial CSF WBC $\times 10^9$/l	5·79	3·402*
CSF cells $>5{\cdot}0 \times 10^9$/l at diagnosis	7	7
Temperature >37·5°C at day 5	5	3
Sequelae	0/8	4/19

*One patient with CSF WBC of $64{\cdot}0 \times 10^9$/l is excluded.

$0 \cdot 024 \times 10^9$/l on day 11, and no sequelae were noted. The initial counts between those with and those without pleocytosis overlapped. The initial mean CSF glucose content was appreciably lower in the pleocytosis group (0·3 compared with 1·9 mmol/l; 5·4 compared with 34 mg/100 ml), but again the two groups overlapped. The initial CSF protein content was similar in the two groups.

Patients with persistent pleocytosis had more lumbar punctures performed (5 compared with 1), were given antibiotics for a longer period (22 compared with 15 days), and spent longer in hospital (32 compared with 17 days), than those without pleocytosis. This prolonged time in hospital was due only to the abnormal CSF cell content. Temperatures were over 37·5°C after 5 days of treatment in 5 of the 9 babies with persistent pleocytosis, but in only 3 of the 27 without such pleocytosis. Apart from persistent pyrexia, however, the clinical course was similar in the two groups. Relapse did not occur in any of the 37 babies. Eight of the 9 with pleocytosis were re-examined after 1½ to 5½ years. None had a residual neurological deficit or a clinically significant hearing loss. 19 of the 27 without persistent pleocytosis were seen after 1½ to 4½ years. Four of these 19 had long-term complications. One girl who had many convulsions during her meningitis has moderate mental handicap and a left hemiparesis. One has mild mental handicap. One has severe unilateral deafness. The 4th had ataxia which disappeared after 3 years. Whether this was cerebellar or vestibular in origin is not known.

Discussion

In two recent reports attention was drawn to the occurrence of persistent CSF abnormalities after apparently adequate treatment of meningitis (Chartrand and Cho, 1976; Jacob and Kaplan, 1977). One-third of the patients with haemophilus meningitis in this survey had CSF white blood counts $>0 \cdot 050 \times 10^9$/l after adequate treatment. This pleocytosis was not associated with a longer clinical illness or with more complications. Nor did it presage a higher incidence of sequelae. It was related to the initial CSF white blood count and glucose content.

The CSF white blood count at diagnosis is not related to the CSF bacterial content (Feldman, 1976). It is, however, an indicator of the patient's response to infection. Also, the CSF glucose level in meningitis is related to brain metabolism and the degree of meningeal inflammation rather than to the CSF bacterial content (Menkes, 1969). Thus, persistent pleocytosis may indicate a better inflammatory response by the patient.

In the series of haemophilus and pneumococcal meningitis reported by Chartrand and Cho (1976), sequelae were present in one of 13 patients with persistent pleocytosis, whereas they were found in 3 of 15 patients without such pleocytosis. This tendency to fewer sequelae if persistent pleocytosis is present is also shown in the present survey. Thus, persistent pleocytosis may be a good prognostic finding. A recent report (Lindberg *et al.*, 1977) had suggested that chloramphenicol with ampicillin may result in more sequelae. Of 22 patients with haemophilus meningitis treated with both antibiotics in this series, none had sequelae.

When clinically indicated, a lumbar puncture is mandatory. Even if it is clear a second lumbar puncture may be indicated within a few hours (Rapkin, 1974). Repeat lumbar punctures may also be warranted at any stage during treatment if indicated by the clinical condition. However, a lumbar puncture after 10 to 14 days in this series did not contribute any useful information from the patients' point of view; for instance, no case of relapse or failure to sterilise the CSF was found. On the contrary, it tended to result in longer treatment and more time spent in hospital. A lumbar puncture may also be hazardous. Thus, in a clinically well child who has received 10 days of appropriate antibiotic treatment, routine performance of a lumbar puncture is not justified.

I wish to thank Dr P. Deasy for his helpful advice and Mrs A. McAlinden for her patience.

Confirmation of gestational age by external physical characteristics (total maturity score)

JOHN I. CATER

Department of Child Health, Ninewells Hospital and Medical School, Dundee

SUMMARY The use of the total maturity score (TMS) as a means of estimating gestational age was assessed in a population of 76 low birthweight infants (≤2500 g) and 80 matched controls (>2500 g) all of certain gestational ages. The gestational ages, derived from the last menstrual period and from the TMS, were similar except in preterm low birthweight infants. The discrepancy in this group was attributed to the structure of the scoring system. It is concluded that the TMS is a convenient and accurate method of assessing gestational age in term babies.

Considerable research has recently been devoted to evolving methods of corroborating gestational age as calculated from the date of the last menstrual period (LMP). These range from the use of ultrasound, *x*-rays, and amniotic fluid estimations during pregnancy, to biochemical and clinical procedures in the newborn. The last method can be divided into three main groups—biochemical, anthropometric, and nonanthropometric. The most widely used are external physical characteristics (Farr *et al.*, 1966), neurological signs (Robinson, 1966), or both (Dubowitz *et al.*, 1970).

The purpose of the study reported in this paper was to assess the use of the total maturity score (TMS) (Farr *et al.*, 1966) in a total low birthweight (LBW) population as a means of estimating gestational age as derived from the date of the LMP. Particular attention was paid to its accuracy in preterm LBW infants.

Method

The infants studied were a sample from a larger survey of low birthweight babies (Cater, 1978) and comprised LBW infants ≤2500 g and their matched controls of normal birthweights (>2500 g). All were of certain gestational ages and each infant was examined by J.I.C. It was fundamental to the study that J.I.C. should not know the length of gestation as stated by the mother and that the maternal history be assessed by an obstetrician, thus ensuring an independent decision concerning the accuracy of the maternal data.

The method recommends that the baby should be examined between 12 and 36 hours of age. The mean age for examination of the controls was 22·1 ± 7·6 hours; total LBW 23·2 ± 13·1 hours; LBW 24·8 ± 17·6 hours; and term LBW 21·7 ± 7·0 hours. There was no significant difference between the mean age at examination of preterm LBW infants and controls. The preterm infants were examined at a later age because of the higher incidence of illness in them.

Results

The data are presented and analysed in broad categories of controls and total LBW, with more detailed subdivision into preterm LBW and term LBW to reveal any weakness of the method. In other studies the results have been combined and presented for a single group, thus concealing the difficulties posed by the preterm subgroup.

The gestational age was derived from both the LMP and the TMS and the difference between the two methods was compared (Table). The only significant difference was found in the preterm LBW group in which the mean gestational age derived from the LMP, 32·9 weeks SD 2·9, differed from that derived from the TMS, 34·4 weeks SD 3·0 ($P < 0{\cdot}05$), a difference of 1·5 weeks. Comparison of the mean gestational ages derived from the LMP and TMS for the other three groups showed no statistical differences. The wide SD found in the total LBW group reflects the influence of the preterm LBW group.

Table *Comparison of the mean gestational ages in weeks calculated from the last menstrual period (LMP) and from the total maturity scores (TMS) in babies whose mothers were certain of their dates*

	Controls (n = 80)		*Total LBW (n = 76)*		*Preterm LBW (n = 36)*		*Term LBW (n = 40)*	
	Mean	*SD*	*Mean*	*SD*	*Mean*	*SD*	*Mean*	*SD*
Gestational age								
Derived from LMP	40·1	1·0	36·1	3·2	32·9*	2·6	39·0	1·1
Derived from TMS	40·4	1·0	36·6	3·2	34·4*	3·0	38·6	1·8

*P<0·05.

Discussion

External physical characteristics as a means of assessing gestational age were preferred to neurological signs for two reasons. Firstly, the sample was biased towards LBW, and therefore many infants would be attached to intensive care equipment, making impossible a number of tests needed for the neurological examination; secondly, it was felt that neurological signs might be altered by the delivery process and drugs given to the mother.

A number of methodological problems are evident in earlier studies. Prior knowledge of maternal dates has been a serious difficulty in several, where the investigator has both examined the baby and questioned the mother concerning the details of the LMP. Such a dual role inevitably influences the findings: the maternal menstrual data must be assessed by an independent worker.

The use of a correlation coefficient has been common in previous studies but has not been entirely satisfactory due to the paucity of babies of shorter gestations. In the present sample a relatively large number of preterm babies of known gestational ages (36/156) was included. For this reason the sample was subdivided into preterm and term LBW groups and analysed separately. The analysis highlights the technical problems of the score. It has not always been appreciated by previous investigators that the precision of the TMS varies with gestational age, since 0·9 points represents a week before 30 weeks and 0·8 points equals a week before 32 weeks, whereas at 39 weeks, 3 points represent a week. The difference in the mean gestational age for preterm infants calculated by the TMS method from that derived from the LMP is 1·5 weeks, compared with 0·4 weeks for infants at term, which shows the inaccuracy of the use of this score in the preterm LBW group

The use of external characteristics seems an easy and satisfactory method of assessing the gestational age of the term baby, and the error is well within the range acceptable in other analyses using complex biological investigations. The results for term infants are remarkably consistent, considering the vagaries of maternal memory and the tacit assumption that ovulation occurs on the 14th day of each cycle. In contrast, the results obtained for preterm infants underline the inaccuracies and uncertainty present in methods currently available for corroborating the maternal data in this group. The small numbers of infants, the effects of illness and drugs, type of delivery, and the structure of the score all militate against accurate assessment in these infants, and further study of this problem is needed.

Conclusion

For routine clinical purposes the use of the external physical characteristics is a simple and convenient method for estimating gestational age. It is particularly accurate at term but is less precise for babies of short gestation.

I thank Professor John Dennis for reviewing the maternal data, Mrs Phyllis Easton for technical assistance, Professor R. G. Mitchell for his helpful comments, and Action for the Crippled Child for generous financial assistance.

Dissolution of bilateral staghorn cystine renal calculi

G. RUYSCH VAN DUGTEREN AND J. WIGGELINKHUIZEN

Department of Paediatrics, University of Cape Town, and Renal Clinic, Red Cross War Memorial Children's Hospital, Cape Town

SUMMARY Bilateral staghorn renal calculi in a 7-year-old girl with cystinuria were dissolved over a period of 6 months, using a high fluid intake, urinary alkalinisation, and D-penicillamine. Even in children with extensive cystine urolithiasis, medical management may avert the need for surgery.

Cystinuria is an inherited complex autosomal recessive defect in which there is decreased proximal renal tubular reabsorption of filtered cystine, lysine, arginine, and ornithine. Defective transport of these amino-acids in the gut has also been demonstrated, but the clinical symptoms are related only to the associated stone formation (Crawhall and Watts, 1968). Cystine is the least soluble of all the naturally occurring amino-acids, and crystalluria and stone formation tend to occur when the cystine concentration exceeds the solubility limit of approximately 400 mg/l (±1660 μmol/l) at pH 7·0 and temperature 37°C (Macdonald and Fellers, 1968).

The excretion of cystine in quantities large enough to cause stone formation probably only occurs in homozygotes (incidence ±1:40 000) (Dahlberg *et al.*, 1977). The age of presentation and severity of disease appear to be related more to drinking habits and other factors affecting urinary concentration than to the actual quantity of cystine excreted or the genotypic variants of cystinuria.

We report what we believe to be the first case in which bilateral staghorn cystine calculi in a child were completely dissolved by medical means.

Case report

A 7-year-old girl of mixed ethnic origin presented with recurrent urinary tract infection and haematuria. No member of her family was known to have calculi or other renal problems, but there was an unconfirmed report that the patient had once passed a small stone per urethram. Clinical examination showed no abnormalities. Her urine contained numerous pus cells and red cells, and gave a pure growth of *Escherichia coli*.

A plain *x*-ray showed the presence of bilateral renal staghorn calculi, with clusters of smaller stones in the calyces (Fig. 1). An intravenous urogram showed mild bilateral caliectasis without evidence of obstruction or renal parenchymal damage.

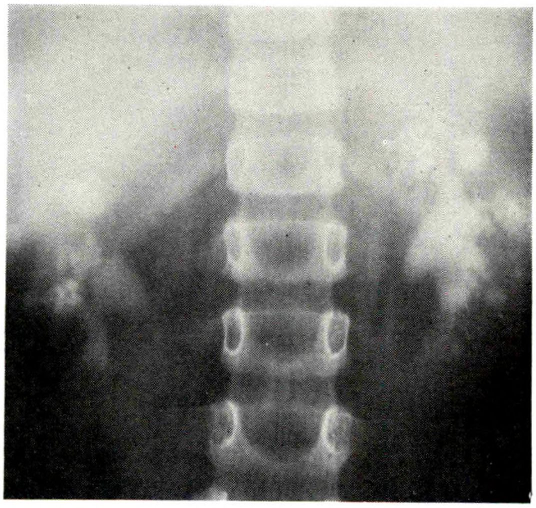

Fig. 1 *Renal tomogram before treatment showing bilateral staghorn calculi and multiple clusters of smaller calculi.*

Serum sodium, potassium, urea, creatinine, calcium, phosphorus, alkaline phosphatase, protein, uric acid, and acid-base values were normal, as were urinary pH and calcium, phosphate, and uric acid excretion values. 24-hour creatinine clearance was 110 ml/min per 1·73 m^2.

Hexagonal crystals typical of cystine were readily demonstrable on microscopical examination of a chilled early morning urine specimen which had been acidified with glacial acetic acid to pH 4. The presence of cystine in the urine was demonstrated by the cyanide-nitroprusside test. High voltage paper electrophoresis confirmed the presence of cystine, and showed abnormally large amounts of the 3 dibasic amino-acids—lysine, arginine, and ornithine. Quantitative amino-acid analysis by ion-exchange column chromatography showed that the patient was excreting >10 times the normal maximum quantity of cystine in the urine—860 μmol per 24 hours compared with the normal adult rate of <80 μmol per 24 hours. The lysine, arginine, and ornithine levels were similarly raised, confirming the diagnosis of homozygous cystinuria.

Cystine excretion by both parents and 2 of the patient's 3 siblings was moderately raised (170–340 μmol cystine per 24 hours). Levels of lysine, arginine, and ornithine excretion were also slightly raised in the father and 2 siblings, but none had radiographical evidence of renal calculi. They are therefore presumed to be heterozygotes.

Treatment and progress

The urinary tract infection was cleared with co-trimoxazole, and prophylactic chemotherapy with nalidixic acid was maintained.

Treatment was directed towards decreasing the concentration and increasing the solubility of cystine in the urine. This was achieved in three ways. Firstly, an increased fluid intake during day and night was encouraged. This effectively doubled the urine output and thus reduced the concentration of urinary cystine. Secondly, by increasing urinary pH from 6 to >7·5 the solubility of cystine was increased approximately 2-fold. 8 g effervescent sodium citrotartrate was given 4 times a day with the additional fluids and was found to be effective in keeping the urine alkaline. The added sodium load (about 200 mmol/24 hours) produced no evidence of fluid overload and had a secondary beneficial effect by inducing an osmotic diuresis. Acetazolamide and sodium bicarbonate were ineffective in keeping the urine alkaline for any length of time. Thirdly, D-penicillamine was given. This drug when excreted in the urine combines with cystine, forming the much more soluble penicillamine-cysteine complexes. The initial dose was 125 mg twice a day and during 3 weeks this was increased to 250 mg three-times daily.

Once the child had been stabilised on this regimen, she was discharged and seen monthly. She remained asymptomatic and no side effects of D-penicillamine or other treatment were observed. Patient (and parent) compliance was excellent as reflected by the passage of large volumes (1800–2300 ml/24 hours) of dilute urine, with a pH never dropping below 7·5.

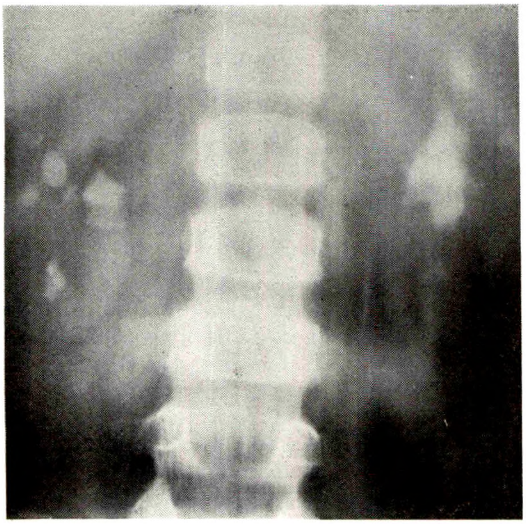

Fig. 2 *Renal tomogram after 2 months' treatment, showing reduction in size and number of calculi.*

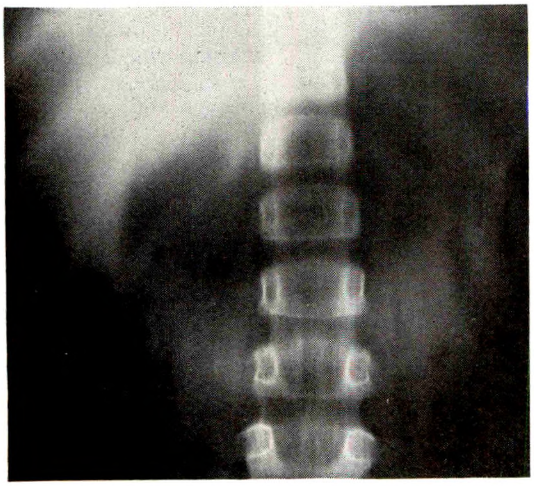

Fig. 3 *Renal tomogram after 6 months' treatment, showing no evidence of calculi.*

Within 3 months of starting treatment the renal calculi were markedly reduced in size and number, and after 6 months these had completely disappeared (Figs 2 and 3). D-penicillamine was then stopped because of the risk of long-term side effects.

Discussion

Nephrolithotomy was initially considered the prime form of treatment. The infection however was readily controlled and as no evidence of obstruction was found, and renal function was normal, immediate surgery did not seem indicated. In addition, the small but definite risk attendant on bilateral nephrolithotomy, and the fact that total removal of multiple calculi is difficult, as well as the inevitability of scarring of both kidneys which would form a nidus for further calculus formation, led us to attempt to dissolve the calculi.

Failure to dissolve calculi may be due to inadequate treatment or to lack of patient compliance: considerable motivation is required to get a child to take extra fluids, especially in the middle of the night. Calculi may also fail to dissolve either because they are mixed stones containing calcium salts due to coexisting metabolic disorders, such as hyperparathyroidism, or because of obstruction to urine flow.

Although medical management is preferable to surgery, it must be remembered that D-penicillamine toxicity is often a limiting factor (Stokes *et al.*, 1968). An acute hypersensitivity reaction with a transient rash, fever, arthralgia, and lymphadenopathy is common but will often resolve if treatment is temporarily reduced or stopped. More serious complications—such as agranulocytosis, immune-complex-induced nephrotic syndrome, drug-induced systemic lupus erythematosus, or Goodpasture's syndrome—usually require discontinuation of the penicillamine. Potential pyridoxine deficiency may be avoided by prophylactic pyridoxine therapy.

To prevent recurrence of cystine calculi, patients will need to understand that high fluid intake especially at night, and probably also alkalinisation of the urine, will have to be continued for life. D-penicillamine is best given only if new calculi are formed (Dahlberg *et al.*, 1977). Less toxic but effective agents, such as N-acetyl penicillamine (Stokes *et al.*, 1968) or mercaptopropyonylglycine (Terhorst and Stuhlsatz, 1975), may become generally available in the near future.

We thank Dr H. Henderson and Dr E. Diamond for amino-acid determinations.

Takayasu's arteritis as a differential diagnosis of systemic juvenile chronic arthritis

EVE ROSSOR

Department of Paediatrics, Northwick Park Hospital, Harrow

SUMMARY After a series of throat infections an 8-year-old girl presented with fever and limb pain, initially diagnosed as juvenile chronic arthritis. Persistent symptoms led to further investigations when she was shown to have an arteritis affecting her aorta.

As there are no specific diagnostic tests for juvenile chronic arthritis (JCA), a remittent fever with a high swinging pattern associated with limb pain which continues for at least 2 weeks tends to be regarded as systemic JCA. However, a number of conditions, including various types of arteritis, can also produce these symptoms (McEnery, 1977).

Case report

An 8-year-old Yugoslavian girl was referred for advice on further management of what was thought to be systemic JCA of 18 months' duration. She was the only child of healthy unrelated parents and had been well until age 7 when, during a 4-month period, she had four episodes of pyrexia to 38°C associated with pharyngitis, which were treated with ampicillin. She subsequently developed fever with a temperature which characteristically reached 40°C daily between the afternoon and midnight, and then subsided spontaneously. She was generally unwell with considerable pain in her lower limbs, but no other signs or symptoms. Initial investigations showed ESR 97 mm in 1st hour, Hb 9·9 g/dl, WBC $13 \cdot 0 \times 10^9$/l, a hypercellular bone marrow, and ASO titre <1/200; blood cultures and all other investigations were negative. Skin and muscle biopsies were normal. She was given a 10-day course of lincomycin and gentamicin but her fever persisted; there was transient improvement with salicylate. Prednisolone was started at an initial dosage of 80 mg daily with pronounced improvement in ESR and fever. Both these parameters deteriorated when prednisolone was reduced to 10 mg daily. She was continued on 10 mg prednisolone daily and aspirin until referred here one year later.

When seen she still had an occasional fever, despite the prednisolone and aspirin. She was markedly cushingoid, and was on the 50th centile for height and the 90th centile for weight. There were no specific complaints but on direct questioning she did admit to some lower abdominal pain, discomfort in the calf muscles, and bleeding haemorrhoids. There were 4 small café-au-lait spots but no other cutaneous lesions. There was no lymphadenopathy, rash, hepatosplenomegaly, or arthritis. Her pulses were easily palpable in the arms and carotids, but no pulses were felt in the femoral arteries or in the legs, which were cold and hairless. No bruit was heard. Blood pressure was 130/80 mmHg in the arms and, by Doppler, 90/0 mmHg in the legs. All other systems were normal apart from first-degree haemorrhoids. Some days after examination it became obvious that the pain in the calves was, in fact, intermittent claudication as it appeared to be closely associated with the child walking some 300–400 metres.

Investigations

ESR was raised at 57 rising to 88 mm in 1st hour on reduction of prednisolone, Hb 12·2 g/dl, WBC

12·3 × 10⁹/l—61% neutrophils, 32% lymphocytes, 6% monocytes, 1% eosinophils; IgA 4·4 g/l (normal 0·5–2·3 g/l), IgM 2·6 g/l (normal 0·5–2·0 g/l), IgG 10·4 g/l (normal); C1q immune complexes were not detected in the serum, complement was normal, renal function was normal. Ultrasound showed an obstruction above the bifurcation of the aorta. Aortography was characteristic of Takayasu's arteritis of type II. There was narrowing of the thoracic aorta associated with a saccular aneurysm (Fig. 1) with incomplete occlusion of the abdominal aorta below the renal arteries and well formed collaterals (Fig. 2).

Management

In view of the already serious involvement of the aorta with persisting disease activity as judged by fever, ESR, and raised immunoglobulins, it was considered justifiable to give cytotoxic treatment. Chlorambucil 0·15 mg/kg was added to the regimen of prednisolone at 10 mg on alternate days. After 14 days of this regimen, the ESR had subsided to 31 mm in 1st hour and the child was apyrexial. She returned home and has continued to do well.

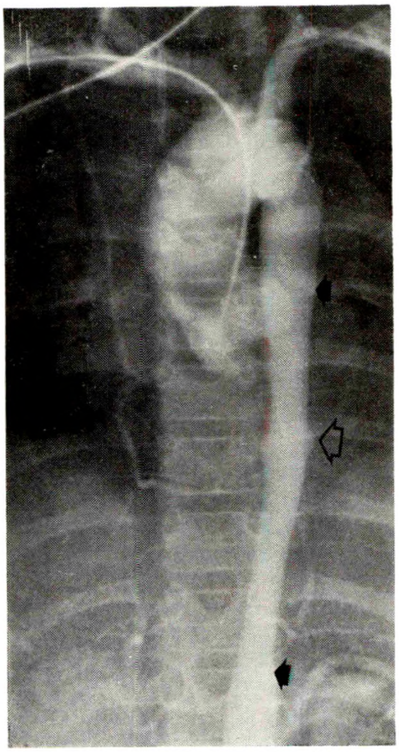

Fig. 1 *Thoracic aortogram. The descending thoracic aorta is diffusely narrowed over a long segment (closed arrows). A small saccular aneurysm is noted (open arrow). All the great vessels are present.*

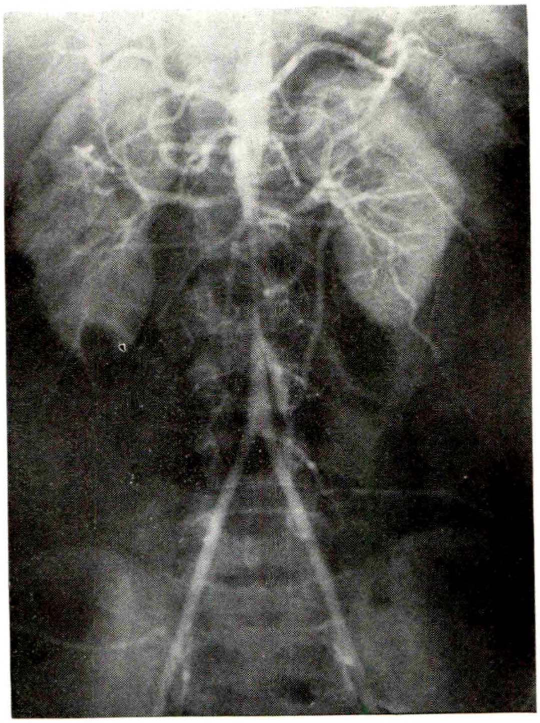

Fig. 2 *Abdominal aortogram. A long segment of the abdominal aorta is diffusely narrowed. Good flow to the iliac arteries is established through mesenteric collaterals.*

Discussion

Takayasu's arteritis is a rare inflammatory disorder affecting the aorta and large arteries in a patchy distribution. It occurs predominantly in females in the 2nd and 3rd decade, although there are several reports of cases presenting in childhood (Lupi Herrera *et al.*, 1977). The pathogenesis is uncertain but autoimmune and infectious causes have been suggested. The pathological changes consist of inflammation in all layers of the wall of the aorta with pronounced intimal thickening. Fibrosis occurs with subsequent narrowing and occlusion of the lumen, and aneurysm formation at weaker areas.

Strachan (1964) has divided the disease process into an acute systemic or prepulseless phase, and a chronic pulseless phase. The systemic phase, which may last for a period of months or years (Strachan *et al.*, 1966), is manifested by a raised ESR and a variety of symptoms suggesting connective tissue disorders. As the pathological process continues, the obstructive or pulseless phase becomes apparent with symptoms such as claudication, weakness, and parasthesiae.

Definitive diagnosis is made at either stage of the illness by arteriography which shows narrowing and/or dilatation of the aorta and its branches. Constrictions of the aorta may be short and segmental or long and diffuse, the latter being common in children in whom the abdominal aorta is often involved. Lande and Rossi (1975) suggested that in this age group the fibrosis limits the growth potential of the aorta, which can then not expand normally, leading to narrowing of the vessels with persistent and often increasing claudication.

The role of corticosteroids and immunosuppressive drugs in treatment of Takayasu's arteritis is not well defined although several reports suggest corticosteroids may prevent progression (Kawai *et al.*, 1978). Should activity not be controlled, particularly in children, in view of a possible aorta growth problem, cytotoxic drugs should be added in an attempt to reduce destruction by the inflammatory process.

This case re-emphasises the need for caution in diagnosing systemic JCA, particularly when joint involvement is inconspicuous. Better identification of the limb pain as ischaemic rather than myositic or arthralgic would have led to earlier diagnosis of the disease process in this case.

I thank Dr R. Wilkins, for performing the aortogram, and Dr B. M. Ansell for permission to describe this case.

How accurate is test-weighing? M. F. Whitfield (introduced by L. S. Taitz). Jessop Hospital for Women, Sheffield.

This study attempted to quantify the error in test-weighing using standard baby scales and ward personnel. Standard Salter 'Trent' baby scales were used to test-weigh 100 bottle-fed infants (mean weight 2·9 kg, range 2·2–4·9), the feeding bottles being similarly weighed, before and after feeding, on a Metzler laboratory balance. The measurements were carried out by nursing staff who normally carry out such measurements.

The systematic weighing errors (1 SD) in test-weights (TW) and feed weights (FW) were evaluated as 13·4 g (100 measurements) and 0·1 g (125 measurements) respectively. Four results were discarded because the TW exceeded the FW by more than 2-fold. In the remaining 96 measurements FW (± 1 SD) was 62·1 ± 16·4 g (range 25–100) and TW 57·24 ± 22·86 g (range 10–130). 32% of the TW was within 10% of the FW; 44% of the TW underestimated FW by more than 10%, one by as much as 87%, and 24% of TW overestimated FW by more than 10%. 73% of the TW was within ± 30% of FW. The regression line TW = 0·77655 FW + 9·02965 calculated for 96 points was not significantly different from TW = FW. At test weights of at least 60 g no significant differences between TW and FW were found, although there was considerable scatter of results (1 SD of FW = 10 g). At TW below 60 g TW underestimated FW significantly (TW = 40 g, n = 26, P<0·001, TW = 20 g, n = 5, P<0·01). The magnitude of the mean TW error was independent of body weight but the error as a percentage of feed weight was greatest in the 2–2·5 kg infants (30%).

It is concluded that test-weighing with standard baby scales at one feed is an inaccurate guide to feed intake, the error increasing in those taking least milk.

Steady-state phenytoin kinetics in children determined from saliva. G. W. Rylance, T. A. Moreland, and R. G. Fowles. Department of Child Health, Ninewells Hospitals, Dundee.

Phenytoin has been widely used in children for many years, but there is little information about its pharmacokinetics in a steady-state. The results of one study suggest that fluctuation in plasma concentration is clinically acceptable if the drug is given once daily (Buchanan *et al.*, 1973). We used saliva phenytoin levels, which show a good correlation with plasma levels in adults (Cook *et al.*, 1975), to determine kinetic data and to assess a once-daily dose regimen. Mixed saliva was collected from 6 children (aged 6–13 years) in a steady-state on a once-daily (0800 h) dose-frequency regimen. Samples were collected at hourly intervals from 0800–2000 h on day 1 and at 0800 on day 2 and assayed by RIA.

The mean half-life was 12·3 h (range 5·0–20·2), the mean clearance was 0·067 l/kg per hour (0·028–0·130), and the mean apparent volume of distribution was 1·15 l/kg (0·29–2·56). The mean steady-state saliva concentration was relatively low, being 2·07 μmol/l (0·77–4·78) on a mean dose of 6·42 mg/kg (4·2–9·7), and the fluctuation in concentration ranged from 152·2 to 363·2%.

The wide interindividual variation in drug elimination rate and the large fluctuation in concentration suggests that dose regimens should be individualised and that once-daily administration is unlikely to be acceptable. Saliva concentration profiles are a convenient and effective means of assessing dose-frequency regimens and investigating drug pharmacokinetics in children.

Hydroxykynurenine hydroxyanthranilic acid ratios in children with febrile convulsions. J. McKiernan, D. Mellor, S. Court, and J. Edson, Department of Child Health, University of Nottingham.

Detection of evidence for demyelination in childhood leukaemia. T. Eden, J. B. Millar, M. Giles, N. Belton, and W. S. Uttley. Royal Hospital for Sick Children, Edinburgh.

Increasing awareness of the potential toxicity of

CNS irradiation and intrathecal medication has led to studies on psychometry and CAT scanning after such treatment. Less interest has been focused on the biochemical changes within the brain and CSF. There have been studies showing disturbance of protein, glucose, and various enzymes during and after treatment. Raised CSF levels of creatine phosphokinase (CPK) have been reported as in neurodegenerative disorders. In one study procoagulant activity in CSF was shown to be increased during CNS prophylactic treatment, and in some patients this remains permanently raised. This activity is probably due to the presence of a lipoprotein factor, derived from myelin breakdown. Combining cytology of CSF with estimation of protein, glucose, CPK, and procoagulant activity on patients receiving CNS prophylaxis, patients with meningeal relapse, and those off therapy, we have confirmed disturbances most notably of procoagulant activity suggesting demyelination. Persistence of the process once all treatment has stopped does appear likely in some cases. We discuss the potential use of measurement of myelin basic protein and 2′, 3′-cyclic nucleoside monophosphate phosphodiesterase (CNP) as more accurate methods of determining disturbances of myelination. All these estimations have practical applications in assessment of the degenerative disorders as well as in leukaemia.

Concept of nonepileptic 'anoxic' seizure threshold and its relation to age. J. B. P. Stephenson. Royal Hospital for Sick Children, Glasgow.

Approximately 130 children had seizures induced by ocular compression in the supine position, as a diagnostic and therapeutic measure in provoked convulsions. The relation of the duration of asystole to the duration of EEG flattening, if present, allows mathematical derivation of 'anoxic' seizure threshold. This threshold is low in early childhood and increases with age.

Assessment of oral therapy in vitamin B12-responsive methylmalonic acidaemia. I. Auchterlonie, G. Russell, Hazel Thom, and D. J. Lloyd. Department of Child Health, University of Aberdeen.

Methylmalonic acidaemia may occur secondary to the impaired synthesis of 5′-deoxyadenosylcobalamin, a cobamid which acts as the coenzyme of methylmalonyl CoA mutase in the conversion of L-methylmalonyl CoA to succinyl CoA. Supplementation of these patients with vitamin B12 leads to an increase in holoenzyme activity and consequent fall in the levels of methylmalonic acid and improvement in the clinical condition. Due to the high doses of B12 required, parenteral administration has been used as first choice, and the oral route is regarded as unsatisfactory. Two recent reports suggest that this latter opinion may no longer be valid, but successful experience with oral treatment remains very limited.

The case is reported of a boy now aged 2½, diagnosed as having methylmalonic acidaemia at age 7 months after admission with severe dehydration and acidosis precipitated by infection. There was a 6-month history of vomiting and failure to thrive. Diagnosis of methylmalonic acidaemia was based on both increased urinary output of methylmalonic acid (21 mmol/l) and impaired propionate/methylmalonate metabolism in skin fibroblasts. Treatment with parenteral B12 produced a rapid and complete clinical recovery and he was maintained on intramuscular B12 1 mg weekly. At age 2 he was gradually changed on to increasing doses of oral B12 and is at present receiving 4 mg daily with a g/g creatinine ratio of 3 on a 2 g/kg protein intake.

Serial measurements of lung mechanics and thoracic gas volume for babies born vaginally and by caesarean section. A. W. Boon. A. D. Milner, and I. E. Hopkin. Department of Child Health, Nottingham University.

Previous studies have demonstrated differences in the lung volumes of babies born by caesarean section, compared with those born vaginally, in the first 6 hours (Milner *et al.*, 1978). The study was undertaken to determine the time for the lung mechanics and thoracic gas volume (TGV) of babies born by section to reach the values of vaginally-born babies.

Serial measurements of lung mechanics and TGV were made in 15 babies born by elective section, and results compared with those of 31 babies born vaginally. The most striking difference was in TGV in the two groups. During the first 48 hours after delivery TGV in the babies born by section approached that of the vaginally-born babies. There was also a tendency for the section babies to have higher resistances and lower compliances than the vaginally-born babies, these differences disappearing after 48 hours.

The differences in the section babies are attributed to an increased volume of lung fluid which is gradually absorbed by pulmonary lymphatics.

Posture and ventilation in low birthweight infants. A. A. Hutchison, K. R. Ross, and G. Russell. Department of Child Health, University of Aberdeen.

In two groups of healthy low birthweight infants, one preterm and one light-for-dates, respiratory mechanics was measured in the prone, supine, and right lateral postures. No difference due to posture were noted in the light-for-dates group.

In the preterm infants the values for elastic work, inspiratory viscous work, total viscous work, total work of breathing, tidal volume, and minute volume were greater in the prone position than in the supine. There was no difference between those results obtained in the lateral position and those in the prone and supine. Thus, in comparison with the supine position, the prone but not the lateral position resulted in an improvement in ventilation. The prone position is recommended for healthy preterm infants.

Small bowel mucosal changes in asymptomatic children with coeliac disease on gluten-free diets. P. J. Congdon, J. M. Littlewood, A. Crollick, and M. K. Mason. Department of Child Health, St James's University Hospital, Leeds.

33 asymptomatic children with biopsy-proved coeliac disease were re-evaluated while on a gluten-free diet. They had been referred from paediatricians for repeat jejunal biopsy and at this time their degree of gluten withdrawal was assessed by a dietitian. Certain laboratory investigations were also made to see if mucosal relapse could be predicted.

Of 33 intestinal biopsies only 15 were normal and 8 showed evidence of severe partial villous atrophy or subtotal villous atrophy. 10 kept to a strict gluten-free diet (GFD), but 12 admitted to frequent dietary lapses. Those on a strict GFD generally had normal biopsies (8/10) while 9 of 12 with regular dietary lapses had abnormal jejunal biopsies. Blood folate and 1-hour xylose levels failed to detect those with persisting mucosal abnormalities. It is advised that close liaison be maintained with a dietitian, and as continued gluten ingestion may be harmful, that repeated intestinal biopsies should be obtained to identify those with confirmed histological abnormalities.

Lactose malabsorption assessed by hydrogen breath testing in acute gastroenteritis. A. J. Gardiner, M. J. Tarlow, I. Sutherland, and H. G. Sammons. Department of Paediatrics and Child Health, University of Birmingham, and Department of Clinical Chemistry, East Birmingham Hospital.

Lactose intolerance is described as an important feature of acute gastroenteritis. Its frequency in infant gastroenteritis in Western society is unclear, although it appears to be of major significance in developing countries (Lifshitz *et al.*, 1971).

Hydrogen breath testing has been validated in adults as a technique for diagnosing sugar malabsorption (Newcomer *et al.*, 1975). After a sugar load, bacteria in the terminal ileum and colon metabolise unabsorbed sugar, releasing hydrogen which diffuses through the gut wall and is transported to the lungs, from where it is excreted in the breath. 43 breath tests were performed on 38 infants with clinically diagnosed acute gastroenteritis. The infants were studied at 0–32 days after the onset of the illness, at a time when they were still thought to need hospital treatment. In 9 cases a bacterial or viral pathogen was isolated from the stools.

An initial group of 20 children was given a lactose load of 0·5 g/kg. None of the children had symptoms of lactose intolerance, but 3 showed a rise in breath hydrogen. After this, 18 children were tested with a conventional lactose load of 2 g/kg. One demonstrated an increase in stool frequency, and the stools contained 0·5% reducing substances on Clinitest. Eight of the 16 children showed a rise in breath hydrogen. In none of these was any clinical symptom detected.

We conclude that clinical lactose intolerance is appreciably less common than biochemical evidence of lactose malabsorption in infant gastroenteritis as found on hydrogen breath testing. Our experience suggests that it is of less significance in Birmingham than reports of tropical infant gastroenteritis would suggest. Management regimens in temperate, developed countries should therefore be modified from those used in the tropics.

Raised hepatic copper concentration in Indian childhood cirrhosis. M. S. Tanner, B. Portmann, C. F. Mills, and A. P. Mowat. St George's Hospital and King's College Hospital, London, and the Rowett Research Institute, Aberdeen.

Indian childhood cirrhosis (ICC) is a disease of unknown aetiology, usually presenting with abdominal distension in infancy, and rapidly progressing to jaundice, ascites, hepatocellular failure, and death. We recently described a new histological feature of the disease, namely prolific coarse orcein-staining granules in both hepatocytes and proximal renal tubular cells, and suggest that these may represent copper-binding protein (Portmann *et al.*, 1978; Tanner *et al.*, 1978).

In a further series of Indian children with liver disease, in whom a clinical and histological diagnosis of ICC was made, 5 had extremely high hepatic copper content (mean 1389 μg/g dry weight; normal <55). 14 children with other hepatic diseases had normal or only slightly raised values, with the exception of one child with cholestasis in whom a value of 292 μg/g was found. We therefore suggest that ICC is caused by a grossly raised hepatic copper concentration, the origin of which may be either an abnormally high copper intake, or an inherited abnormality of copper metabolism similar to Wilson's disease. The fact that ICC is limited in its distribution to the Asian subcontinent suggests the former, an environmental aetiology. In 4 of the 5 cases, the family cooked or stored water in vessels made of brass or bittall (an alloy containing copper).

These results raise the exciting possibility that this almost universally fatal disease may be entirely preventable.

Transpyloric feeding in 32 babies undergoing intensive care. Elizabeth Dryburgh. General Infirmary, Leeds.

Transpyloric feeding, using commercially available silicone tubes (Vygon Ltd), is described in 32 newborn infants undergoing intensive care. 30 babies required assisted ventilation; 2 had undergone surgery for upper small bowel atresia. Gestational age ranged from 26–42 weeks (mean 32). The technique of passage of the tube, and the difficulties encountered are described. Transpyloric tubes were passed on 49 occasions in 28 (94%) babies. 80 *x*-rays to confirm the tube position were required (1·7/passage, 2·3/infant). Placement of the tube at operation was carried out in 2 babies with small bowel atresia. Attempts to pass the tube were abandoned in 2 infants. The feeding tubes remained *in situ* for 1–43 days (mean 10).

During the first 7 days of life 20 infants transpylorically fed lost weight (mean 18 g/day). In the others the weight remained static. After 7 days all babies fed by this route gained weight (mean 35 g/day).

The most common complication (39%) was accidental displacement of the tube. Transient diarrhoea (23%) and vomiting (6%) also occurred. Necrotising enterocolitis was suspected clinically in 2 (6%) infants but was not confirmed by *x*-ray.

How clean does breast milk have to be for feeding raw to babies on SCBU? L. Carroll, M. Osman, and D. P. Davies. Departments of Child Health and Microbiology, Leicester Royal Infirmary.

At present there is considerable debate over the practicalities and safety of feeding pooled raw (unheated) breast milk to babies on special care baby units (SCBU) (*British Medical Journal*, 1978). Of particular concern is the bacterial contamination which might be allowed. Recently proposed bacterial criteria for feeding raw breast milk were largely empirical (Williamson *et al.*, 1978) and did not take into account the bacterial flora of breast milk which is taken by the normal breast-fed baby. 207 samples of breast milk from 70 mothers were collected in sterile universal containers by a clean-catch method. Each sample was collected between the 4th and 7th days. The mothers were not taking antibiotics nor were they applying antiseptic cream to the breasts. The milk samples were delivered to the laboratory within one hour of collection. Serial dilutions of milk between 10^{-1} to 10^{-4} were made in nutrient agar (Oxoid) using a semiautomated analyser, and after overnight incubation at 37°C the numbers of colony-form units per litre (CFU/l) were determined. 170 (82%) samples grew only skin-commensal organisms (coagulase-negative staphylococcus and *Streptococcus viridans*) in numbers ranging from 10^5–10^{10} CFU/l. 13 (6%) grew *Staphylococcus aureus*, 15 (7%) enterobacteriaceae, 3 (2%) group B streptococcus, and 6 (3%) produced no growth.

A feature of this study is the heavy bacterial contamination of breast milk taken by the normal suckling infant. We propose that milk contaminated by *S. aureus*, enterobacteriaceae, and group B streptococcus needs to be pasteurised before use, but breast milk containing only skin-commensal organisms in numbers up to 10^{10} CFU/l may be given raw.

Prophylaxis against early onset group B streptococcal septicaemia. D. J. Lloyd, T. K. Belgaumkar, K. E. Scott, A. J. Wort, K. Aterman, and V. W. Krause. Departments of Pediatrics, Obstetrics, Microbiology, and Pathology, Grace Maternity Hospital and Dalhousie University, Halifax, Nova Scotia.

Between January 1969 and May 1974, 11 of 1208 low birthweight infants developed early onset group B streptococcal (GBS) septicaemia. All 11 infants were <35 weeks' gestational age and 9 presented with the clinical and *x*-ray signs of RDS. 10 of the 11 infants died. Antibiotics were given to 3 infants only, but not before age 12 hours. From June 1974 infants <35 weeks gestational age and from January 1977 all infants <2500 g, received systemic penicillin by 2 hours of age after throat, ear, umbilical, rectal, and blood cultures. Penicillin was continued for 10 days if GBS was isolated but was stopped at 48 hours if cultures were negative. Between June 1974 and May 1978, there was one case of septicaemia in the 1143 low birthweight infants born during this period but none has died from GBS. These data suggest that systemic penicillin from birth will prevent the mortality from GBS in low birthweight infants ($\chi^2_1 = 7{\cdot}65; 0{\cdot}01 > P > 0{\cdot}001$).

Follow-up of children of diabetic mothers. Mary Cummins and Mary Norrish. Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital, London.

To be published in full in the *Archives*, 1980, **55.**

Follow-up of children of mothers with chemical gestational diabetes. Anne Reid, G. Russell, H. W. Sutherland, P. D. Bewsher, and J. M. Stowers. Departments of Child Health, Obstetrics and Gynaecology, Therapeutics and Clinical Pharmacology, and Medicine, University of Aberdeen.

Three groups of children whose mothers were diagnosed as having chemical diabetes during pregnancy and who were treated at that time with chlorpropamide 100 mg daily, with insulin, or without the use of drugs, were reviewed to determine if there was any difference between these groups of children recognisable on follow-up, and attributable to the effect of maternal treatment on the fetal islets in terms of physical growth, neurological and intellectual development, and β-cell function. A control group of 43 healthy children was established for the interpretation of the oral glucose tolerance test used to assess β-cell function. The growth of these children was normal except for a slight tendency to underweight-for-height in the girls of mothers who received no treatment. No child was seriously handicapped neurologically, although 2 children were mentally retarded and required special schooling, one in the insulin group and one in the no drug group; one child in the chlorpropamide group has bilateral neurosensory deafness. There was no difference found in the intellectual ability of the three groups of children.

There appeared to be a significant impairment in glucose tolerance of children of mothers treated with insulin compared with a control group. This was not explained completely by either the age difference of the children at follow-up or the degree of maternal glucose intolerance in pregnancy. Three of the chlorpropamide group have required treatment for their diabetes.

Hormonal and auxologic patterns in boys with constitutional growth delay. M. O. Savage, J. L. Penfold, M. A. Preece, Y. Cyranka, J. Jones, and M. D. Mansfield. Department of Growth and Development, Institute of Child Health, London.

Serum LH and FSH responses to LHRH (100 μg IV) were measured in 24 boys with constitutional growth delay. Basal plasma testosterone (T), androstenedione (A), and dehydroepiandrosterone (DHA) were also measured in 16 of these children. Two groups of boys were defined: (1) prepubertal (mean chronological age (CA) 11·8 years, bone age (BA) 9·5 years, height SD score −3·2, and mean testicular volume (MTV) 2ml), and (2) early pubertal (mean CA 14·7 years, BA 12·3 years, height SD score −3·7, and MTV 3–8 ml).

Peak LH response to LHRH was greater in group 2 (mean 8·7 IU/l) than in group 1 (mean 2·9 IU/l). In 8 out of 9 prepubertal subjects with a bone age of <10 years peak LH response was <2 IU/l. There was no difference between FSH responses (4·8 and 3·8 IU/l respectively). Basal T levels were low in prepubertal subjects whereas A and DHA increased from a BA of 8 years. These findings suggest firstly, that the LHRH test is of limited value in the diagnosis of gonadotrophin deficiency in the early prepubertal period and, secondly, that a normal temporal relationship of gonadotrophin and adrenal androgen secretion with bone age is present in boys with constitutional growth delay.

Parental and medical assessment of symptoms during infancy. A comparative study of hospital admissions and unexpected home deaths. A. N. Stanton, P. M. McWeeny, A. Jay, E. Irwin, and J. R. Oakley. Princess Mary Maternity Hospital, Newcastle upon Tyne.

The symptoms and medical contacts of 150 infants surviving acute hospital admission were compared with those of 100 infants dying unexpectedly at home, with histories of major terminal symptoms. Half of each group had been ill for more than 3 days. Specific symptoms (apart from coughing) were relatively rare among home deaths, but both groups generally had nonspecific behavioural changes. The severity of the illness, with physical signs stressed more often than symptoms, determined referral in half the cases admitted after primary care assessment. 31% of these families were considered by the GP to have delayed their consultation. The remaining referrals were partially related to families' inability to cope adequately with their children's illness. Initiative for follow-up had been left to the parents in 94 (87%) of the 108 cases not admitted at first consultation, although 44% of these families already wanted their children admitted. Only 39 of the home deaths had been medically assessed, 17 within 24 hours of death, including two prearranged follow-ups. As parents often sought medical help inappropriately, and 23% of all families expressed hesitation about contacting their doctor, it is suggested that daily professional reassessment should be considered normal practice when infants have major symptoms.

Use of an objective clinical examination in assessing medical students' practical skills in paediatrics.

T. Waterson, Ninewells Hospital, Dundee.

The assessment of students' skill at performing certain clinical techniques has always been difficult, as examiners tend to confine themselves to standard areas—such as the detection of signs and the interpretation of data. Despite the widely held view that the ability of junior doctors in such procedures as urine testing and history taking is inadequate, these areas are seldom covered in clinical examinations which are overwhelmingly subjective in their method of appraisal.

This paper describes the results from a type of assessment not previously used in paediatrics, the Objective Structured Clinical Examination (Harden *et al.*, 1975). In this examination students rotate round a number of different stations at each of which they spend 4 minutes and perform a standard procedure—such as taking a limited history, examining one particular area, interpreting *x*-rays, or testing urine. Alternating stations assess the student's analysis of his findings by multiple-choice questionnaire; examiners also observe the student and mark his performance from a check list at some of the stations. 18 final-year students were assessed in this way and figures are shown from some questions in the examination, of which examples are given. Table 1 shows the results in 4 individual questions and Table 2 correlates these results with those in the examination as a whole. Students' performance in urine examination was particularly poor and the implications for this in improved teaching are discussed.

Table 1 *Results (abbreviated) in four questions*

Question	*Mark % (mean ± 1 SD)*
A	74 ± 11·7
B	72 ± 20·1
C	41 ± 14·5
D	74 ± 15

Table 2 *Correlation of results*

Question	*Mark %*	*r*
Total (whole paper)	75 ± 5·9	X_2
A	74 ± 11·7	0·66
B	72	0·47
C	41	0·005*
D	74	0·24

A = Examiner's check list on history of vomiting, B = MCQ on history of vomiting, C = MCQ on urine testing, D = MCQ on *x*-ray interpretation. * Significant at 0·001 level

Students learn best those subjects they know they will be examined on; this technique allows a particular area of clinical performance to be assessed objectively and it is therefore a valuable teaching aid.

Congenital nephrogenic diabetes insipidus

Sir,

Schreiner and co-workers reported a baby girl with congenital nephrogenic diabetes insipidus (NDI) (*Archives*, 1978, **53**, 906). I should like to contribute a case diagnosed as having partial NDI.

This boy had been transferred from a local hospital at age 9 months because of high fever with high serum Na and Cl concentrations, initially noticed in the first week of life. His mother showed polydipsia and polyuria: her urine osmolality after water deprivation for 12 hours was 270 mmol/kg. Investigation of the patient showed high serum osmolality (315 mmol/kg), low urine osmolality (100 mmol/kg), serum Na 172 mmol/l, and serum Cl 126 mmol/l.

Subsequently clearance studies were performed while the boy was receiving both a normal and a salt-restricted diet, after water deprivation, and after intravenous DDAVP (Aronson and Svenningsen, 1974). The main results were: (1) On water deprivation the patient was able to concentrate urine up to 600 mmol/kg simultaneously with reduction of urine volume; after DDAVP (0·4 ml IV) urine volume decreased further; osmolar clearance, which had increased during water deprivation, decreased after DDAVP. (2) On normal diet and on salt-restricted diet DDAVP resulted in increasing osmolar and free water clearance (and urine volume).

We made the following interpretations on the effect of DDAVP (a synthetic vasopressin analogue) on our patient's kidneys: renal resistance to DDAVP was incomplete; there was an adequate response after giving DDAVP during water deprivation, whereas a paradoxical effect on osmolar and free water clearance (Brodehl *et al.*, 1965) was apparent during the control periods.

Partial NDI (McConnell *et al.*, 1977) was diagnosed and treated by salt restriction and frusemide (15 mg/day). Follow-up 3 years later shows uncomplicated physical and psychological development of the patient with normal or almost normal values for serum Na, Cl, urea nitrogen, osmolality, and bicarbonate. Urine osmolality ranged from 200 to 265 mmol/kg.

I wonder if Schreiner and co-workers would like to comment on our patient, particularly with regard to their own therapeutic experience.

Myotonic dystrophy and bonding failure

Sir,

In their report of 5 cases of the neonatal form of dystrophia myotonica (*Archives*, 1979, **54**, 331), Pearse and Höweler emphasise the ethical problems facing the clinician once the diagnosis has been made, and they discuss the need for genetic counselling. We should like to add support to their concern for earlier diagnosis by drawing attention to another important and potentially lethal hazard run by babies with this condition—that is bonding failure. If they survive the neonatal period, these babies must always be considered to be at increased risk of rejection and neglect. Not only are they likely to have accumulated a number of the features commonly associated with child abuse—for example, neonatal separation, early ill health, maternal physical and emotional illness (Lynch, 1975; Lynch and Roberts, 1977)—but both mother and child are further handicapped by the inability to use facial expression effectively as a means of communication.

This was well illustrated by a family referred to the Park Hospital in Oxford. The parents were both very young and came from unhappy and divided homes, thus the potential for abuse was high. The mother's relationship with her own mother was hostile yet dependent, and the father had experienced a rigid authoritarian upbringing. When we met the mother she was just 20 and had had two caesarean sections within 13 months. Her second son had been very ill in the neonatal period, spending the first 7 weeks of his life in the special care baby unit. He had required assisted ventilation for some days. During his stay in the unit the diagnosis of myotonic dystrophy was made both in himself and his mother. A distaff family history of dystrophia myotonica was discovered, with the mother's own mother, the grandmother, and a great aunt suffering from cataracts and facial diplegia. It was also found that the elder brother had a milder form of the disease.

When finally discharged home, the baby had a floppy, expressionless face; he made none of the grimaces and little noises a normal baby makes. His abnormal cry was quiet and ineffective; his smile did not appear. Feeding was a nightmare. Much of his time he slept 'like a dead baby', making him easy to 'forget' and his mother was terrified that he would die silently without her noticing. She was at a further disadvantage by her own inability to use facial expression as a means of communication with her baby. Soon all those concerned in the baby's care, including the mother herself, were fearful for the baby's safety and help was sought before there was serious neglect or abuse.

The family were then admitted to the Park Hospital for an intensive period of treatment where the mother learned to make appropriate signals and respond to her baby. Both mother and child could gaze fixate, even though it could not be coupled with smiling. Starting from this, the mother was helped to recognise the more subtle signs from the baby, such as tiny mouth movements and slight panting sounds in her presence. The baby, too, was encouraged in making chuckling noises in response to his mother's gaze. Marital therapy was also required and it was interesting to note that in the mother's family all the sufferers of myotonic dystrophy had had broken marriages. Several years later, this family remains united but the parents still require help from both health and social services in bringing up their 2 young handicapped children.

Early use of sodium nitroprusside in respiratory distress syndrome

Sir,

Beverley *et al.* (*Archives*, 1979, **54**, 403) reported the response to sodium nitroprusside in an infant with hyaline membrane disease, and I should like to make some comments on their patient.

The course of the illness, with the infant not requiring added oxygen and only very low ventilator pressure by 24 hours of age, must cast doubt on the diagnosis of surfacant-deficiant hyaline membrane disease, and suggests that the baby was suffering from the after effects of severe birth asphyxia, the early problems of intrapartum pneumonia, or perhaps from some iatrogenic disease.

During the time sodium nitroprusside was being infused, 3 other major changes in treatment took place which may have been responsible for improving the baby's condition. Firstly, his pH was corrected. The effect of this on pulmonary perfusion and pulmonary vascular tone is well known, and could itself be responsible for the improved oxygenation in the infant. Secondly, the inspiratory to expiratory ratio was reduced from 4:1 to 1·5:1 and while we do not know the ventilator pressures that were sustained during this period, it seems likely that this would be associated with a considerable fall in the mean airways pressure. Particularly in infants without hyaline membrane disease, a high mean airways pressure can be responsible for serious pulmonary underperfusion, and lowering the airways pressure as was done in this patient, can be associated with a large increase in arterial Po_2. Thirdly, they transfused their patient, and while we are given no blood pressure data before this was started, the fact that they were able to increase the baby's blood volume by more than double suggests that, irrespective of the hypotension-producing effect of the nitroprusside, the infant was previously hypovolaemic or hypotensive, or both. Correction of that could also be responsible for an improvement in the infant's condition and oxygenation.

I would submit therefore that Beverley *et al.* have provided absolutely no evidence for a beneficial effect from sodium nitroprusside in their patient, and that before this comparatively dangerous drug is used, evidence that it improves oxygenation while other factors in the treatment are held constant is required. This, for example, has been provided for tolazoline (McIntosh and Walters, 1979).

Department of Paediatrics,
Addenbrooke's Hospital,
Hills Road, Cambridge CB2 2QQ

Sir,

The letter from Beverley *et al.* (*Archives*, 1979, **54**, 403), and the report by Abbott *et al.* (1978) to which they refer, should both be treated with extreme caution. In neither is a good case made for the use of sodium nitroprusside to reduce pulmonary vascular resistance (PVR) in severely hypoxic newborn babies. While Beverley and colleagues refer to the known hazards of this hitherto untried drug, they give no details of the state of the circulation or of the $Paco_2$ during their infant's first few hours. These are important since poor tissue oxygenation and hypercapnia may both contribute to acidosis, and PVR in the newborn may be expected to increase as pH falls (Rudolph, 1977). The extreme acidosis at 2–4 hours of age was presumably the legacy of severe birth asphyxia.

Nevertheless, the information provided suggests that after a blood transfusion (which should have improved tissue oxygenation) and during the slow correction of the severe acidosis, there was initially a steady fall in right-to-left shunt, followed at the age of 11 hours by a more rapid improvement in both the arterial pH and $Paco_2$.

There is no evidence that sodium nitroprusside had any effect other than, possibly, to cause systemic hypotension. Similarly, the paper by Abbott *et al.* (1978) merely serves to illustrate the importance of correcting acidosis and hypercapnia early in the course of neonatal respiratory distress. Moreover, their case illustrates the ill-advised use of sodium bicarbonate as a buffer in a hypercapnic neonate whose minute ventilation is fixed by mechanical ventilation. Their figure clearly shows a *worsening* of hypercapnia and a *fall* in pH after bicarbonate infusion.

It is clear that the primary aim of therapy in severely hypoxic neonates suffering from RDS should be to attempt to correct those metabolic derangements which promote pulmonary vasoconstriction. It would be dangerous to conclude from the currently available literature that sodium nitroprusside has any value in such patients.

Dr Beverley and co-workers comment:

The clinical and radiological appearances in the small preterm baby we described gave us a working diagnosis of RDS, and contrary to Dr Roberton's impression we stated that at 24 hours old the baby still required added oxygen as well as intermittent positive pressure ventilation (IPPV). We accept that birth asphyxia may have contributed to the severity of his illness.

We agree that correction of metabolic derangements which may provoke a rise in pulmonary vascular resistance (PVR) is important in the management of RDS and are sure that increasing Pa_{O_2} and tissue oxygenation is of paramount importance in making this correction. In our case correction of arterial pH was unlikely to have been due to bicarbonate infusion, as <1 mmol bicarbonate had been infused by 12 hours of age when the baby's arterial pH was 7·4. We agree that injudicious use of bicarbonate may be detrimental. Hypercapnia was not a significant contributory factor to the acidosis nor was the high PVR. Pa_{CO_2} in our baby ranged from 3·5 to 6·4 kPa (26·3 to 48 mmHg) during the period of IPPV. Neither was hypovolaemia or hypotension before the use of nitroprusside suggested by continuous measurement (via the umbilical artery catheter) of arterial blood pressure, by the small core-peripheral temperature gradient, or by the failure to improve after the initial 20 ml transfusion at 4 to 5 hours old. The subsequent transfusions were given over a 5-hour period in response to downward trends in arterial blood pressure and widening core-peripheral temperature gradients after starting nitroprusside.

We wish to emphasise that the ventilator settings at the start of the nitroprusside infusion were those which produced the maximum Pa_{O_2} and that subsequent changes were made in response to improvements in the infant's condition and were not the cause of them.

We accept that it is advantageous when studying the effects of a drug to keep other factors in the treatment constant, but this may not be possible when the drug is being infused over a period of time and may indeed be contraindicated.

Our original letter drew attention to the possible toxic effects of nitroprusside and stressed the need for careful biochemical and blood pressure monitoring during its use. Since then we have used nitroprusside in 5 other infants with severe RDS with beneficial effects in all cases and feel that further study of its use in this condition is warranted.

Role of gastrin in pyloric stenosis in infants

Sir,

The careful clinical study by Hambourg *et al.* (*Archives*, 1979, **54**, 208) evaluating serum gastrin levels in infants with hypertrophic pyloric stenosis adds further evidence minimising the role of gastrin in the production of this disorder. Although Hambourg *et al.* quite properly indicate that there is controversy about preoperative fasting gastrin levels in infants with hypertrophic pyloric stenosis when compared with controls, most authors have agreed that there is no significant increase of this hormone. Two major questions remain unanswered: (1) Is there excessive *in utero* exposure to gastrin in these infants? (2) Is there a possibility of excessive postprandial hypergastrinaemia in these infants? The first question has been addressed by a study (Werlin *et al.*, 1978) in which levels of circulating gastrin were measured in umbilical venous blood and maternal venous blood obtained at delivery in 40 infants who subsequently developed hypertrophic pyloric stenosis. In this comparison, there was no significant difference between the mean cord and maternal gastrin concentrations of infants subsequently developing pyloric stenosis, and normal infants. The possibility of excessive postprandial hypergastrinaemia in these infants was addressed in a recent clinical study from our institution (Moazam *et al.*, 1978), and has been confirmed by Hambourg's work. In our study, 11 patients with congenital hypertrophic pyloric stenosis were evaluated with sequential pre- and postprandial serum gastrin levels immediately before pyloromyotomy and 2 to 10 weeks later. When compared with an age-matched control, the fasting gastrin levels in our patients (125 ng/l) were identical with the control (128 ng/l). The gastrin responses to a Sustagen meal (providing 1·7 g/kg protein) were likewise similar. The finding of a somewhat flattened postprandial gastrin curve in Hambourg's infants after pyloromyotomy is most likely explained by residual antral stasis. As these authors properly point out, radiological evidence of impaired gastric emptying frequently persists in the immediate postoperative period in these patients. We would agree with the conclusions of these authors that there is no evidence to support the hypothesis that patients with pyloric stenosis have an abnormal gastrin mechanism.

Florida 32610, USA

Dr Hambourg and co-workers comment:

We agree with the conclusions of Dr Rodgers and Dr Moazam although the results of their recent study are not comparable with ours (Moazam *et al.*, 1978). Regarding the curve showing changes in serum gastrin levels after ingestion of a high protein meal (Sustagen, providing 1·7 g/kg protein) these authors obtained a slope that increased more slowly from baseline values. Moreover the peak gastrin values were noted in control infants at 45 min, and in patients with hypertrophic pyloric stenosis at 30 min preoperatively and 45 min postoperatively. Analysis of the decreasing slope was not described. Our study was performed by administering a casein hydrolysate (Amirige, providing 0·7 g/kg protein) containing free amino-acids. In 11 control infants and 10 patients with pyloric stenosis the mean peak gastrin level was noted within the first 10 minutes after the feeding, showing a maximum value at 10 min and a return to basal gastrin levels after 60 and 90 min. The differences may be explained by differences in the two methods. Certainly high protein preparations are capable of producing a gastrin release. However hydrolysed proteins, especially free amino-acids, were found to be more potent gastrin stimulants (Elwin, 1974), thus increasing the accuracy of the test. Our results with the gastrin secretion test show the importance of recording the serum gastrin levels within the first 10 min after feeding and continuing to record it for at least 60 min. In the study by Moazam *et al.* (1978), 11 infants with pyloric stenosis were evaluated with postprandial serum gastrin levels before pyloromyotomy and 2 to 10 weeks after surgery. Interestingly, a gastrin secretion test was performed on patients with untreated hypertrophy of the pylorus. In the postoperative studies a similar rise in serum gastrin concentration was noted in response to protein ingestion, however no significant differences were observed from preoperative studies.

In our patients, increased fasting gastrin levels were noted after pyloromyotomy and were still present 2 weeks after the operation. The postoperative hypergastrinaemia may be explained by a residual antral stasis on the 7th and 15th days after surgical pyloromyotomy, represented by a postprandial gastrin curve with a 'levelling-off' effect between 30 and 60 min, as Dr Rodgers and Dr Moazam clearly point out. Nevertheless, in these two studies test meals did not produce an exaggerated gastrin response, and the results were of the same order as those obtained by the same trial control stimulation. Therefore we agree that there is no evidence that patients with pyloric stenosis have an abnormal gastrin mechanism.

Book reviews

Colour Atlas of Clinical Conditions in aedodontics. By R. Rapp and G. B. inter. (Pp. 142; illustrated. £12.00 rdback.) Wolfe: London. 1979.

his is the first coloured diagnostic atlas paediatric dentistry to be published. It is ot meant to be comprehensive but a sual guide to many abnormalities and seases of the hard and soft tissues ncountered in the oral and facial uctures of children and adolescents.

The opening chapter is divided into ctions based on the anatomical features f the head and is largely concerned with evelopmental anomalies of the cranium d face. With the aid of excellent colour ictures and *x*-rays, it illustrates a series of normal conditions with their variations, ch succinctly described in brief accompanying paragraphs giving the salient atures.

The second chapter is the longest and overs abnormalities of the teeth with eference to number, size, shape, structure, d colour. Although some sections may e of greater interest to paedodontists, aediatricians will find the beautifully lustrated descriptions of anomalies of oth structure and colour especially luminating as a number of these are trogenic. The coverage of gingival and eriodontal conditions in chapter 3 is good ut may prove confusing if taken in olation. Chapter 4 deals with the lips, lveolar mucosa, cheeks, and floor of outh including congenital, infective, and aumatic conditions. Many of the lustrations amplify conditions partially escribed in earlier sections. Except for the ection on clefts, chapters 5, 6, and 7 erely add a little to the diagnostic pictures lready seen and are probably of greater nterest to dentists.

It was an inspired act to have a chapter n the limbs. The illustrations and content eally do fulfil the authors' intention hat '. . . . they either complete a clinical icture of, or are closely related to . . . .' onditions already described in the atlas.

It would be wrong to claim that this ook is above criticism, especially for the aedodontist who may feel it is incomplete nd wishes it contained some rather more haracteristic examples of certain conditions. Nevertheless, it should prove an excellent book for medical and dental students and clinicians, providing an easily usable reference book to assist in the recognition and diagnosis of oral and dental disease.

EILEEN C. JAFFE

British Paediatric Association Classification of Diseases (in two volumes). By BPA. (Vol. 1: Pp. 220. Vol. 2: Pp. 94, index. £4.00 for the two volumes, paperback.) BPA: London. 1979.

There must be people for whom the classification of disease represents the ultimate challenge of scientific medicine. As one who is happy to leave all classification to others, I approached these volumes with trepidation.

The aim of the Health Statistics subcommittee of the BPA in preparing the new classification of diseases was to design a supplement compatible with the ninth revision of the WHO *International Classification of Diseases*, but modified to be of use specifically in paediatric and neonatal departments. The 3-digit main *ICD* code is followed by a 1- or 2-digit subcode. The first 4 digits of the code in the paediatric supplement are compatible with the *ICD* and only the fifth digit is specific to the paediatric classification. It is pointed out in the introduction that the general use of such a unified coding system will greatly facilitate data retrieval for preparation of health statistics or research purposes.

The first volume shows the layout of the codes and is divided into 16 chapters according to type of condition, areas of the body affected, or stage of life at which a condition may occur. The second volume comprises an alphabetical index of diseases with the appropriate codes. For coding purposes the alphabetical index alone should be sufficient, although it is intended that it will be used in conjunction with the main *ICD*.

The new supplements are far more comprehensive than the old *Cardiff Diagnostic Classification* which they replace. However, the only test of such a classification is to determine how easily and efficiently it can be used in practice.

Unfortunately I ran into trouble on my first attempt to use it for coding disease in the newborn because there are no codes appropriate for periventricular leucomalacia. As this is one of the most common and important forms of brain damage in preterm infants and is now diagnosed in life using computerised axial tomography it seems a pity that there is no code for it. Other codes were found moderately easily as soon as the quirks of the index were recognised. The dislike of compilers for multi-indexing means that the structure of a particular index has to be understood before it can be used. In this one for instance, rhesus iso-immunisation appears under 'incompatibility—(blood)', and hyaline membrane disease under 'syndrome—respiratory distress (idiopathic)'. This is extremely irritating to the occasional user like myself who would prefer an alphabetical list three times as long that would enable him to find a condition under whichever name he cared to look, rather than having to guess where it will have been listed. The index will however prove stimulating to clerical staff who revel in the nuances of inside-out alphabetical listing and may even learn to code periventricular leucomalacia under 348·1 ('Anoxic brain damage. Excludes: when of newborn'), until the next revision is published.

Despite these criticisms the codes do represent a worth-while advance and should of course be introduced by all paediatric departments. If users keep the BPA informed of any problems they encounter there may be hope that, in the future, an optional idiot-proof version will be made available for those of us who find indices difficult to use.

J. S. WIGGLESWORTH

Liver Disorders in Childhood. Postgraduate Paediatrics Series. By A. P. Mowat. (Pp. 407; illustrated + tables. £18.50 hardback.) Butterworth: London. 1979.

I have been able to assess the usefulness of this book as a source of clinical reference in dealing with the relatively small numbers of hepatic problems coming my way. It is predictably good, both because Alex Mowat writes from a depth and breadth of experience of paediatric liver disorders unique in this country, and because he writes well.

It is a pleasantly compact volume to handle, the print and reproductions are clear, and it is well illustrated with photomicrographs, line drawings, and clinical photographs. References are generous and some as recent as 1978 are included.

Two introductory chapters discuss the anatomy and physiology of the liver and biliary tract, perhaps a little too briefly. Hyperbilirubinaemia, conjugated and unconjugated, is the subject of the next two chapters. Clinical conditions giving rise to jaundice in infancy are clearly set out, and by using the tables and checklists of possible diagnoses, the general paediatrician is unlikely to overlook treatable causes of the neonatal hepatitis syndrome. Practical advice on a suitable and humane programme of investigation is given, including a basic outline of surgical techniques for appropriate cases.

Subsequent chapters deal with infections: hepatic failure, Reye's syndrome (an excellent review and guide to management), toxic and metabolic disorders, genetic, structural, and biochemical disorders, cirrhosis, cystic fibrosis, tumours, and vascular abnormalities. The developing world is not forgotten, and specific chapters deal with sickle-cell anaemia and Indian childhood cirrhosis. I particularly appreciated the final chapters in which methods of investigating liver and biliary function are discussed.

There are an irritatingly large number of typographical errors: for example on p. 59, phenobarbitone is referred to as an enzyme 'reducer' when 'inducer' was surely intended. The index is mainly adequate, but it eschews some eponyms in common use (for example, Alagille disease, Byler disease) whose correct titles are long and difficult to remember, and therefore to find. There will surely be further editions in which these small defects can be remedied. At £18.50, reasonable in 1979, this book is an excellent investment. It has been worth waiting for.

J. A. DODGE

Pediatric Orthopedic Radiology, volume 15 in the series Saunders' Monographs in Clinical Radiology. By M. B. Ozonoff. (Pp. 516; illustrated. £22.50 hardback.) Saunders: Eastbourne. 1979.

I am sure that most radiologists' hearts sink when they are faced with an awkward problem in paediatric orthopaedic radiology, The trouble owes much to the fact that the two disciplines have so little in common that the respective specialists are not aware of the others' difficulties.

Dr Ozonoff is in a unique position to bridge the gap between the orthopaedic surgeon and the radiologist: he is Director of Radiology at Newington Children's Hospital in Connecticut and has also had experience in orthopaedic surgery.

The book catalogues the disorders of childhood which affect the skeleton, the first chapters dealing with specific parts of the skeleton and the later ones with generalised disorders. This makes for easy use of the book: none of the searching that bedevils reference to books written by committees is necessary. Most of the sections on specific disorders are masterpieces of brevity and lucidity. The current thinking is presented with relevant recent references. Indeed many sections could be read with equal reward by orthopaedic surgeons or radiologists.

The section on the normal hip is most valuable. The host of measurable variants, lines, angles, and levels are described and, what is most important, their significance is given due weight. One or two readers may baulk at the lines drawn along the femoral shafts to show the Von Rosen sign in Figs 3–8 B but this must not be allowed to detract from the overall impression of reliability; I am sure the section will be used to settle many viewing-room arguments. Hip arthrography in congenital dislocation discovered late is strongly advocated. There are few who would condemn this procedure out of hand, but many British surgeons feel that the information gained is frequently spurious and that the extra irradiation is only justified in cases of unusual difficulty.

The book is densely packed with information and cannot be read quickly. It is a work of reference of remarkable authority and depth. It will prove a most valuable book to radiologists and orthopaedic surgeons who deal with children.

MICHAEL WATSON

Toys and Playthings in Development and Remediation. By J. and E. Newson. (Pp. 279; illustrated. £1.50 paperback.) Penguin: Middlesex. 1979. A hardback edition, price £7.95, is available from All
and Unwin: London.

In their latest book John and Elizabe
Newson have taken a long and detail
look at the part played by toys in t
developmental progress of young childre

The combination of simple language and straightforward line drawings has made the

ABC OF OPHTHALMOLOGY

one of the most popular series of articles in the Medical Practice section of the British Medical Journal.

All the common problems are covered - visual defects, squints, glaucoma and cataracts - together with detailed instruction on examination, diagnosis and management.

The articles have now been collected into book form - in exactly the same format as they appeared in the BMJ - price: Inland £2.50; Overseas US$6.25 (Inland £2.00; Overseas US$5.00 for BMA members).

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751; 1978, **53**, 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1**, 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Apart from any relaxations permitted under national copyright laws, no part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means without the prior permission of the copyright owners. Permission is not, however, required to copy abstracts of papers or of articles on condition that a full reference to the source is shown. Multiple copying of the contents of the publication without permission is always illegal.

He might feel better if you played detectives.

The allergic component in the aetiology of childhood asthma is well recognised. Tracking down the specific offending allergens, however, is quite a detective job. Skin testing gives only a rough idea. Nasal and bronchial provocation tests can be difficult to interpret, risky or far too time consuming.

Phadebas RAST is the laboratory test that can eliminate a lot of suspects and identify the villains by revealing individual sensitivities reflected in high levels of specific IgE in the blood.

With Phadebas RAST, one ml of serum can give you a reliable profile of the most probable clinical sensitivities — a better guide to successful treatment.

Send off the coupon and examine the evidence.

Phadebas RAST®
In-vitro test for atopic allergy.

IMPORTANT NEW BOOKS

Paediatric Cardiology Volume 2
Heart disease in the newborn
Edited by M. J. Godman and R. M. Marquis
1979 520 pages illustrated hardback £20.00

Contains information on research currently being done in centres in the USA, Canada, UK, Netherlands, Germany, France, Spain and Sweden. The emphasis is on problems occurring in the first 4 weeks of life.

Secretory Otitis Media and its Sequelae
Jacob Sadé
1979 334 pages illustrated hardback £19.50

Covers the research done within the last 20 years on one of the most important and prevalent of paediatric illnesses.

Aphasia, Alexia and Agraphia
D. Frank Benson
1979 320 pages illustrated hardback £13.00

A clinically orientated discourse on the neurogenically derived problems of language.

NEW EDITION
The Normal Child
Some problems of the early years and their treatment
Ronald S. Illingworth
1979 Seventh edition 368 pages illustrated hardback £8.00

FORTHCOMING PUBLICATION
The Orthopaedic Management of Spina Bifida Cystica
Malcolm B. Menelaus
1980 Second edition 304 pages approx. illustrated hardback £25.00 approx

Churchill Livingstone
Robert Stevenson House, 1-3 Baxter's Place, Leith Walk, Edinburgh EH1 3AF

Current Paediatric Cardiology

Elliot A. Shinebourne and Robert H. Anderson

Advances in the diagnosis and treatment of congenital heart disease have led to the situation where all but a small minority of anomalies can be successfully treated even in infancy. Because the subject has developed so rapidly there is a need for a concise up-to-date book suitable for paediatricians, cardiologists, and advanced students. Besides discussing individual anomalies the authors and invited experts review general topics related to congenital heart disease. Illustrated £12.50 *Oxford Medical Publications.*

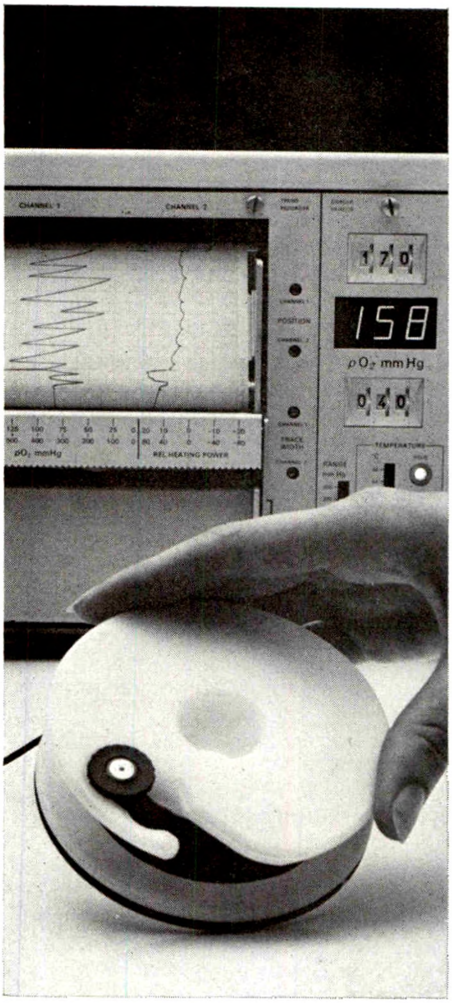
Taking blood oxygen measurement is as simple as this.

The Draeger
ymeter gives you
nplicity with precision.
The vital job of
taining blood oxygen
easurements is a
mple, straightforward
ocedure with the
raeger oxymeter.
It's entirely non-
vasive and non-
aumatic and there is no
sk of blood infection or
rombosis.
It's simple. The
ectrode is attached to
e skin, a few minutes
lowed for warm-up;
d the reading is
ailable.



It's precise.

Several published papers attest to this.

And it's stable. Precise measurement is maintained over long periods of use and response to pO_2 fluctuations is swift.

The Draeger oxymeter is a valuable aid in monitoring patients in neonatal and adult intensive care.

It s value will be more than apparent when you have read the literature and we'll be pleased to send you copies as soon as you ask

PEDIATRIC RESEARCH

Volume 13, No. 9 September 1979

Contents

The Zinc, Copper, Manganese, Vanadium, and Iodine Content of Hair from 38 Canadian Neonates 000

R. S. GIBSON AND M. S. DEWOLFE (Halifax, Nova Scotia, Canada

This investigation was undertaken to establish "normal values" for the zinc, copper, manganese, vanadium, and iodine concentrations of hair in 38 full term neonates.

Parathyroid Hormone Response in Newborn Infants during Exchange Transfusion with Blood Supplemented with Citrate and Phosphate: Effect of iv Calcium 111

P. WIELAND, G. DUC, J. A. FISCHER, AND U. BINSWANGER (Zurich, Switzerland)

The authors attempt to investigate parathyroid secretory function in newborn infants before, during, and after exchange transfusion and to assess whether iv calcium supplementation can prevent the decrease in serum ionized calcium as well as the prolongation of Q–oTc intervals during exchange transfusion with donor blood preserved in citrate and phosphate

Protease Inhibitors in Human Milk 222

T. LINDBERG (Malmo, Sweden)

This investigation reports the occurrence, electrophoretic properties, and amounts of some protease inhibitors in human milk from birth to 4 months after delivery.

Serum Concentration of 24, 25-Dihydroxyvitamin D in Normal Children and in Children with Rickets 333

T. M. NGUYEN, H. GUILLOZO, M. GARABEDIAN, E. MALLET, AND S. BALSAN (Paris, France)

This paper describes the method of 24, 25-$(OH)_2D$ measurement in serum and reports the results obtained in normal children as compared with normal adults, in children with Vitamin D deficiency or Vitamin D-resistant rickets, and in one child intoxicated with ergocalciferol.

Ketotic Episodes in Glutaryl-CoA Dehydrogenase Deficiency (Glutaric Aciduria) 444

N. GREGERSEN AND N. J. BRANDT (Aarhus and Copenhagen, Denmark)

The finding of metabolites derived from the catabolism of branched-chain amino acids and the fatty acid in urine samples from a patient with glutaryl-CoA dehydrogenase deficiency indicate an inhibition of acyl-CoA dehydrogenases in the patient.

The Effect of Sleep State on Chest Distortion and on the Ventilatory Response to CO_2 in Neonates 555

M. DAVI, K. SANKARAN, M. MACCALLUM, D. CATES, AND H. RIGATTO (Winnipeg, Manitoba, Canada)

The prevalence of chest distortion and the ventilatory response to CO_2 was measured during non-REM and REM sleep in neonates.

Effect of Cigarette Smoke Exposure on Maturation of the Antibody Response in Spleens of Newborn Mice 666

H. B. HERSCOWITZ AND R. B. COOPER (Washington, D. C.)

These results indicate that the maturation of the splenic antibody forming cell response in developing mice was significantly inhibiting as a consequence of exposure to cigarette smoke.

The effect of Diazepam Upon the Development of Hypertension in the Spontaneously Hypertensive Rat 777

R. M. SCHIEKEN (Iowa City, Iowa)

This study describes the long-term antihypertensive effects of the chronic administration of diazepam to young spontaneously hypertensive rats (SHR).

Effect of Hydrocortisone on the Metabolism of Phosphatidylcholine in Maternal and Fetal Rabbit Lungs and Livers 888

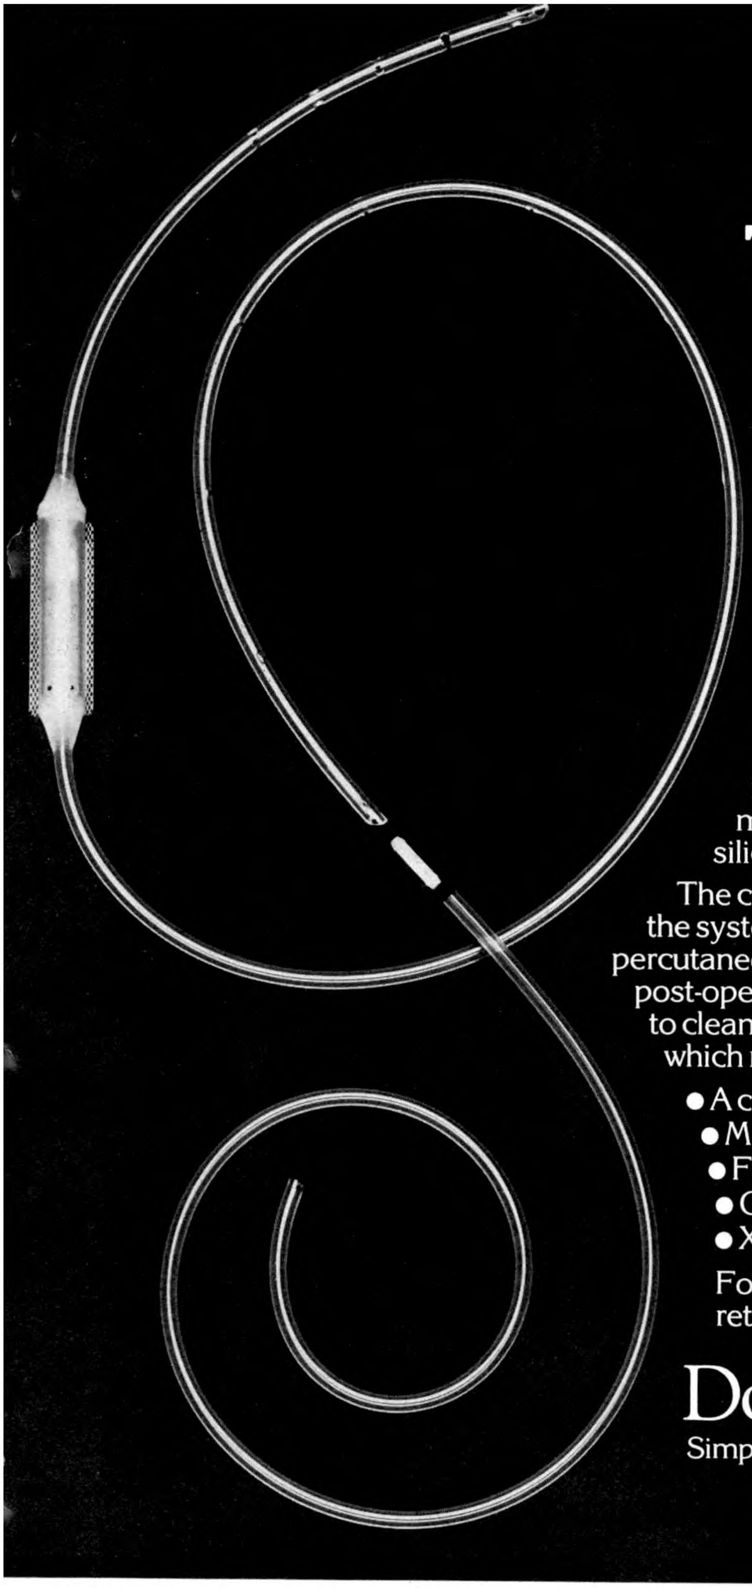
F. H. C. TSAO, G. R. GUTCHER AND R. D. ZACHMAN (Madison, Wisconsin)

This investigation was undertaken to examine the effects of antenatal maternal steroids on phosphatidylcholine (PC) metabolism in maternal lung and liver in comparison with effects on fetal PC metabolism.

A Study of Inheritance in Progressive Intrahepatic Cholestasis: Hepatic Excretory Function in Unaffected Family Members 999

P. BIDOT, D. R. LABRECQUE, Y. E. HSIA, AND C. C. A. RIELY (New Haven, Connecticut)

In an attempt to identify the heterozygous state for PIC hepatic excretory function was studied in the parents and four second degree relatives of two brothers with PIC.



The Denver Peritoneo-venous Shunt

For the effective control of Ascites.

The heart of the Denver System is a one-way silicone rubber valve which is contained in a soft pump body, also made of medical grade silicone rubber.

The construction allows the system to be pumped percutaneously, to confirm its post-operatively patency or to clean it of any obstruction which may enter the system.

- A choice of placement
- Minimal tissue reaction
- Four flow rates available
- One-piece construction
- X-ray markers

For full details just return the coupon.

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

Archives of Disease in Childhood

is available to junior hospital doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following reduced rates are unchanged for the twelve issues published in 1980.

Inland £17.00

Overseas US$40.00

(The full rates are: Inland £29.00; Overseas US$70.00)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

Editorial

Douglas Gairdner, editor of the *Archives* 1964–79

This special number of the *Archives* is dedicated to Douglas Gairdner by the editors with whom he has worked, the *Archives* staff, the Editorial Committee, and the staff of the *British Medical Journal*.

Since its foundation in 1926, the *Archives* has had 10 editors, who have nearly always worked in pairs. As the list below shows, Douglas Gairdner has been the longest serving, with 16 years in office, followed by Richard Dobbs with 15. Separately and together these two editors have guided the *Archives* for half its life span.

When Douglas joined the *Archives* in 1964 it was published bimonthly. About 180 papers were offered each year and each volume comprised about 600 pages. Publication is now monthly, over 600 papers are received annually, and there are about 1000 pages per volume. The process of scrutiny, refereeing, and editing of papers has become much more exacting for editors and authors alike in the intervening years.

Douglas has been distinguished in many fields—as a clinician, as a research worker of continuing originality over 30 years, and of course as an editor. In 1976 he was awarded the James Spence Medal, the highest award of the British Paediatric Association. In 1978 he received the Dawson Williams Memorial Prize of the British Medical Association for his creative editing of the *Archives*. A brief biographical note, and the lively personal appreciation which Professor Donald Court delivered in presenting the James Spence medal, were published in *Archives* 1977, **52,** 85.

In this issue the personal appreciations refer to Douglas as an editor and friend, and the special annotations are a tribute to the extraordinary breadth and variety of his research interests.

Editors of the *Archives*:

Hugh Thursfield and Reginald Miller, Vols 1–8, 1926–33

Charles Harris and Alan Moncrieff, Vols 9–13, 1934–38

Alan Moncrieff and R. W. B. Ellis, Vols 14–20, 1939–45

R. W. B. Ellis, Vols 21–22, 1946–47

R. W. B. Ellis and P. R. Evans, Vols 23–24, 1948–49

Archives of Disease in Childhood, 1979, **54**, 815–816

Personal tributes

Douglas as editor

RICHARD DOBBS

Douglas Gairdner joined me as editor of the *Archives of Disease in Childhood* after Ian Cathie resigned in 1964. I nominated Douglas not only because of his medical, paediatric, and literary abilities but also because of his attitude to sailing. Both require an ability to make quick decisions and to take actions which in every sense of the word may have vital consequences. This appreciation of Douglas, at that time one of my crew, and in recent years substantiated when I became one of his crew, arose through his capacity, when faced with an important decision, to ask for opinions, to which he gave careful thought, and then to take decisive action. This, to one who is essentially an impulse sailor, augured well for the important discussions and decisions that need to be taken by the editor of a journal receiving a constant flow of contributions which arrive, like the waves on the sea, out of the blue and which, however light or weighty, need to be carefully assessed.

A newly created journal needs to grow up, and for some years remains a financial burden to its parent organisation. Since its conception in 1926, the *Archives* has been the property of the British Medical Association who financed its birth, infancy, and childhood. During our joint editorship the *Archives* passed through its adolescence, and began to pay its own way. In 1970 discussions began as to whether the British Paediatric Association, which since 1945 had nominated the editors and editorial committee, and to which many of the contributors to the *Archives* belong, should benefit from the profits of the journal. Douglas Gairdner representing the editors of the *Archives*, and I, no longer editor, representing the BPA as its president, remained convinced, paediatrics being not a specialty, but general medicine for a special age group, that the *Archives* and its editorial staff should remain in close association with its elder brother, the BMJ, and the editorial staff continue to benefit from friendly contact with colleagues of all the numerous medical journals housed on the same floor in the same building; and so the journal remained the property of the British Medical Association and the BPA began receiving an annual grant from the profits. During the ensuing years under the editorship of Douglas Gairdner and Roger Robinson the *Archives* has prospered and grown, is now published monthly, and receives increasing contributions from countries outside the British Isles. In 1977, after further discussions between the BPA and the BMA, in which Douglas took a major part, an agreement was signed whereby the two organisations were joint partners in the journal.

An editor of a medical journal not only accepts or rejects papers but himself adds editorial comments, and Douglas has made many notable contributions. Soon after the war he wrote his classical paper on anaphylactoid purpura, which many of us still think of as Gairdner's version of the Henoch and Schönlein condition; and perhaps a more important impact on medical practice, he was one of the first to point out that circumcision is the major one of 3—now 4 or even 5—medically unnecessary operations; this was followed by its gradual elimination, at least as a regular initiation heralding the emergence of the neonate into infancy. Then recently he recounted in the *Archives* an interesting fable regarding a child who survived a 'near fatal' condition, with serious chronic complications, and, who, over six decades later, Douglas assures us is still alive and sufficiently kicking, to be taken on as a sailing crew.

Douglas Gairdner 'retired' from the NHS in 1974 but hasn't noticeably slowed down. In addition to a variety of activities in Cambridge, advising in the local Citizens' Advice Bureau, and playing the tuba in the Royston Brass Band, he has added to his weekly visit to the *Archives* office an outpatient teaching session at the Queen Elizabeth Hospital for Children in the east end. Here, as a senior member of the medical staff commented, the students from the London and St Bartholomew's Hospitals enjoy his shrewd and perceptive medicine, and no one really believes, either from his physical appearance or his teaching style, that he has yet reached retiring age. His colleagues in the editorial office have lively memories of his scarlet-lined waistcoats, his curly blond hair under a yachting cap, and his endearing but maddening habit of leaving his scarf, gloves, brief-case, etc., on trains between Cambridge and London. It is abundantly clear that both he and his wife, Nancy, an enthusiastic physiotherapist, will remain fully involved in life's activities for many years to come.

Archives of Disease in Childhood, 1979, **54**, 817–819

Douglas as editor

ROGER ROBINSON

When I was invited to meet Douglas in 1968 to discuss the possibility that I might join him as editor of the *Archives*, I felt that I was being privileged to meet one of the great names of British paediatrics. As a student, two of the books which had most kindled my interest in paediatrics were the splendid first and second editions of *Recent Advances in Paediatrics*, in which he was both editor and an important contributor. I had also met his name on several important papers—on Schönlein-Henoch syndrome, and on haematology of the newborn. Douglas's constant additions to paediatric knowledge from his own research over the whole of his career remain one of the most remarkable and impressive characteristics of this remarkably impressive man. It must be comparatively unusual to be able to base a number in tribute to a great editor on his own contributions to the literature, but I had no doubt that this was most appropriate for Douglas. My only problem was trying to find all his papers! They have been published in many journals, though he has been very faithful to the *Archives* both before and during his editorship. When I was going through the indices of the *Archives* to locate his contributions since 1948, I started by taking down from the shelves those volumes in which his name appeared. However, it soon became apparent that it was much simpler to take down the volumes in which his name did *not* appear and leave on the shelves the much larger number where it did.

Working with Douglas proved as great a privilege as I had expected, but also full of unexpected pleasures. The alternate Tuesday afternoons of our regular meetings were always occasions to look forward to, and if we had time to meet for lunch beforehand I would be entertained with his conversation which always included sailing but also ranged over archaeology, history, biography, or politics. Douglas is an avid reader of considerable erudition, and would often be bursting with enthusiasm about the book that he had just read on one of these subjects. Human motivation fascinates him, and he would certainly have made a splendid novelist if he had had time to follow five careers instead of just the three or four which he successfully encompassed. What he said was always enlivened by a great sense of humour and by great kindness, something of which I am particularly reminded on looking back over the letters he wrote during our years together as editor.

Whether or not we had a leisurely start to our afternoon's editing, there was always a great deal to discuss and do, and the pace of work and of Douglas's activities would accelerate from about 4.15 pm onwards. At 5 o'clock he would leap up, shoving an armful of papers into a capacious travelling bag (which he regarded as a *sine qua non* for an editor, ordinary brief cases being much too exiguous) and dash out of the office in the curious slightly squashed blue headgear which he called a yachting cap, but which was certainly not Cowes style. One or two things would usually have been left behind, but even in his 70th year his time for the sprint from BMA house to King's Cross would be difficult to beat. Astonishingly, he practically never missed a train.

Douglas's scientific and clinical achievements and his rounded personality have been acclaimed in Donald Court's James Spence medal citation and in the other articles in this special number. I therefore wish to write particularly about his work as editor. Of all the qualities which he brought to this task, the two which impressed me most have been his enthusiasm and conscientiousness. Editing a major journal for 16 years is very hard work. Richard Dobbs compares an editor to the skipper of a yacht, but in some ways I think the editor is more like one of a rowing crew—in the case of the *Archives*, which has a long tradition of two editors working harmoniously together, a coxed pair, the technical editor being the cox. Most editing is a long, steady, hard pull over very similar stretches of water and it is only occasionally that some kind of tidal wave in the shape of angry would-be authors, delays at the printers, or terrible editorial oversights threatens to engulf the boat. New papers come into the office daily—now over 600 a year—and each one is likely to be seen and worked over by the editor several times between its submission and rejection or publication. Every stage on every paper would be dealt with by Douglas with the same scrupulous care.

The popular notion of editors is that they come in two main kinds. On the one hand are policymaking editors, taking a broad view of what the journal should be doing and not too much concerned with details. On the other hand are editorial editors concerned with details of accuracy, style, spelling, and format. If these two kinds of editors exist, Douglas was emphatically both at the same time. He was constantly concerned with the broad responsibilities of the *Archives*. He felt it part of his job to try to obtain the best papers for the journal by keeping his ear to the ground for what was going on in research and being presented at meetings. Could an original paper be encouraged to come our way, or was there some new topic ready to be dealt with in an Annotation or some other special invited article? He was also concerned with trying to take the *Archives* to parts of the world where it was less widely read, and his new ideas for doing this have been a constant theme in the Minutes of meetings of the Editorial Committee over the last 15 years. The ethics of paediatric research is an issue in which he has taken a particular and long-standing interest. He tried to ensure that articles published in the *Archives* met the highest ethical standards and that children were not exploited or misused for research. However, on this subject like all others his view was a balanced and moderate one, and he has also been keen to ensure that proper and beneficial research is protected and not impeded. Of the three policymaking leading articles on this subject published in the *Archives* in the last 12 years, the most important was undoubtedly the 1973 one (Volume 48, page 751), and this was almost entirely written by Douglas.

Douglas's broad editorial grasp was always apparent when we discussed what to do with a difficult paper. Confronted with a lengthy article, often containing unfamiliar technical detail, and a lengthy and detailed referee's report, he would always cut through the befuddlement which is apt to afflict editors in this situation. He would rapidly pick out the main points which the authors were, or ought to have been, making. He would then ask: Was it scientifically convincing? Was it clearly expounded? Was it important? Confusion rapidly vanished.

However, Douglas was also an editor with an irresistible interest in detail and style. A manuscript which he had read—even one we were most unlikely to publish—would always be covered in corrections made either in pencil or in fine ink (the traditional thick blue pencil never seems to have been part of the editorial equipment in this office). All his alterations, his letters to me, and his drafts of letters to authors would be written out in longhand, not always particularly legibly. (Much of Douglas's writing was certainly done on the train between Cambridge and London, but his writing *always* looked as if it had been done on a bumpy train-ride.)

Douglas was particularly appreciative of the invaluable service given to the *Archives* by its technical editors, and he would certainly be very disappointed if this special number did not include a tribute to the splendid work of Rita Carne, Susan Burkhart, and Jennifer Orton, the three who have assisted us during his editorship. However, Douglas's attention to detail, including punctuation and the use of particular words, occasionally led to one of the very few disagreements between him and them. In general, commas are regarded as the property of the technical editors—at least ordinary, common-or-garden, tactical commas which make sentences easier or more difficult to read. Only the much rarer strategic comma which may totally alter the sense of a sentence is regarded as coming within the purview of the editors. But Douglas could sometimes not resist a wholesale attack on commas of all kinds to the consternation especially of Rita Carne. His desire for stylistic accuracy met its Waterloo over a problem related to drug dosage. 'Milligrams per kilogram per day' is an expression in everyday use in clinical medicine. It is of course scientifically and mathematically incorrect, the correct expression being 'mg kg^{-1} day^{-1}'. However, the latter expression is not only a typographical monstrosity but it bears no relation to the colloquial one in clinical use. Douglas chewed over this problem for several years during his editorship. He could not bear the incorrect 'mg/kg/day'. He toyed with various compromises, finishing up with 'mg/kg per day', mainly I think because it at least indicated that we could see there was a problem. However, I believe he still experiences a mild twinge of pain every time he sees this expression printed.

Another stylistic problem which vexed him was that of sibs and siblings. After consulting various genetic experts (who frankly do not seem to have been terribly clear themselves about the distinction between these words), Douglas concluded that the correct term for 'brothers and sisters' was 'sibs', and that 'siblings' was incorrect because it was a diminutive and referred only to children. In the volumes of the *Archives* spanning several years, therefore, the word 'siblings' does not appear unless inadvertently it escaped Douglas's editorial pen. We subsequently discovered that we were quite wrong. 'Siblings' is the correct term for children having one or both parents in common, and 'sib' is a broader and vaguer term connoting kinship. (Interested readers looking up '-ling' in the *Oxford English Dictionary* will find an explanation of why it is not a diminutive in words of this kind.)

Douglas was not particularly put out by this discovery—his occasional conservatism is always blended with a willingness to change in the light of new evidence, and siblings are now to be found in the pages of the *Archives*.

Another example of Douglas's willingness to change even his most cherished ideas concerns the title of this journal. Periodically there are rumblings in the BPA, the Editorial Committee, or just among interested readers, that our title is old fashioned and carries an air of musty Dickensian attics—which is not the image we try to convey. Douglas was always rather fond of the title and was skilled at marshalling arguments in its defence. The truth was that he would have been perfectly happy to change it if someone suggested a better title, but that exercise is a great deal more difficult than it sounds, and so far no one has.

Working for nearly 11 years with Douglas at the *Archives* has been a high privilege and pleasure. The British Paediatric Association, British paediatrics in general, and the journal itself owe him a great debt for all that he has contributed over so many years. However, I will especially remember Tuesday afternoons sitting with him in a smallish room in BMA house at a smallish table piled with papers. About them, and about everything else, he always has something interesting to say.

Archives of Disease in Childhood, 1979, **54**, 820–821

Douglas in retrospect

DERMOD MacCARTHY

For those readers of the *Archives* who have never met Douglas Gairdner he is a tall, good looking man with a very straight back for his age, who carries his head on his shoulders in a youthful manner. He has a slightly Grecian nose and a forehead that is transversely heavily lined, due to moods of levity rather than gravity, as with the creases round his eyes. His hair which was blond has not turned grey or white in his sixties but brown, and being as thick as ever gives a remarkable impression of youth. But, let me say at once, it is not just an impression for he still is in every way extraordinarily young.

It is difficult to describe a man who, because of his capacity to respond to people of all kinds and his liking for intimacy, may present a different image to each of his many friends. Therefore some personal reminiscences must suffice to give an impression of him in the hope that some people will recognise in them resemblances to their own pictures of Douglas.

A few years ago Douglas, when introducing me to someone, added after my name, 'who is my oldest friend'. That warmed me. I could not have wished for an adjective, as a friend, that I liked better. We were both at Gresham's School, Holt and met there about 54 years ago. I remember him then as a good deal smaller than me, although slightly older. When I met him in later years he had shot up. He told me that a late puberty was the reason for this and he always held that it had been an advantage to have been held back by it from his proper age group and then to put on a sprint to manhood at a mentally maturer age. It was much to be recommended, he said. When we met again at Great Ormond Street in 1939 (he a stepping stone or two ahead on the path to paediatrics) we at once started to compare experiences at that puritan but civilised school. I told him that in class we relied on him to bring the master down as David did Goliath. This he did by being sometimes urchin, sometimes puck, imp, buffoon, or leprechaun, 'getting the wires crossed', and of course translating the Latin prose into absurdities which he then defended with many a pained . . . 'but Sir!'. It was very good to find him again and a friendship developed that at school had only been slight. We shared a house in Chelsea until war was declared in September, a delightful 9 months of cooking experiments, music, intimate talk, and flirting with the 'daily'.

At the start of war we were both posted as 'Blood Transfusion Officers' (in anticipation of massive air raid casualties) to the Royal National Orthopaedic Hospital at Stanmore, where an insoluble residue of children from Great Ormond Street had been bundled down to be in comparative safety and where we were to continue to look after them in our spare time. The house in Chelsea was to be left to its fate. It was good bye to all that. We had hurriedly to pack Douglas's car with all our essential belongings and be off. What was 'essential'? That was a good question. There was an exhilaration in discovering that in fact nothing was. I left a great heap of things on the floor unpacked as mere paraphernalia. When we slammed the door and drove off it was a golden afternoon, with a sky that was soon to be blackened by hundreds of bombers. I noticed that Douglas was smiling. Turning round in my seat I noticed his golf clubs rather vulgarly sticking out of the back window. He liked mock heroics.

'Mock obituaries' was a game Douglas invented. We were young and flippant and made fun of the cliché-ridden obituaries of the *BMJ* of the time, doing our own or each other's as we drove from Chelsea to Great Ormond Street in the morning, or employing extravagant 'obituareese' to clap wings on the backs of our dullest contemporaries or most pompous seniors. There was also the 'back to nature obstetrics' game in which Douglas had designed a mock hospital consisting of caves in which women would be delivered in straw, naked of course, and in order to have and to hold the baby immediately would bite through the cord with their teeth; but just to be on the safe side, would undergo a short course of dental hygiene in the antenatal period. Prophetic perhaps?

In our London days we often discussed music and played flute duets, which to be honest were not a great success. Sometimes we played our gramophone records, particularly Nadia Boulanger's marvellous production of Monteverdi's madrigals, something quite new to us and to many young music lovers at the end of the 'thirties. Once, when talking about Handel's Messiah, Douglas made a remark which I was to remember long afterwards; he said how impressed he was by the power of the words in one of the arias . . . 'A man of sorrow, and acquainted with grief'. Warmth and generosity of response to people whether or not in trouble or in need of sympathy we think of as kindness; but an intenser degree of this we would call love. I remembered that remark of Douglas's when, years later, he and Nancy were indeed acquainted with grief, for he became, not a man of sorrow, but one whose kindness was intensified in this way.

Can one distinguish one paediatrician's feelings towards children, as patients, from another's? Yes, of course; but it may be difficult to express it. Douglas always had, quite unsentimentally, a particularly tender feeling for very young children, a feminine as well as a fatherly concern for them, so spontaneous, so beautiful, so vulnerable. He hated seeing them in hospital and in 1956 he gave a paper to the Royal Society of Medicine entitled 'The decline and fall of hospital paediatrics' .Throughout his 27 years at Cambridge he worked with very few beds and could be acclaimed as the paediatrician who admitted the fewest children to hospital and kept them there for the shortest time. It was not his fault that some people, particularly administrators, in the early years of the NHS interpreted the title, and not the substance of his paper, to mean that paediatrics was a dying speciality and that paediatricians, like the tuberculosis officers, were sawing off the branch they were sitting on. We knew what he meant by 'hospital paediatrics'—the child who, no matter how young. languished from week to week in a hospital ward (which was also a sort of museum), between visits of the big chief.

How can one describe him as a man to work with or do things with? The simile that seems most apt for his relationship with others in work or various pursuits is that of first violin in a quartet. Not the grand soloist or the leader of the orchestra but a gifted dominant player, who at the same time feels and needs the music of the other players. In the pages that follow something of this will be appreciated, but for an example of a pursuit, why not take sailing? It is a great test of friendship, loyalty, and niceness or leanings to selfishness. Douglas in a boat is certainly the first fiddle, but how the quartet plays! My first experience of playing under his bow was in 1939, when he knew rather little about it, if I may say so now when he is a great small-boat mariner. The 'Merrythought' was a small shallow-draught yacht. We were 4 aboard. As we sailed out of a little Essex creek towards the sea she suddenly slowed down, then stopped. Instantly we were ordered overboard to shove her off the mud. Stripped to the waist, that is from below upwards, and with shirt tails floating on the turbid water, we pushed and heaved until away we went, clambering aboard with long black stockings, or tights in one case, which we were ordered to wash off before being allowed in the cockpit. But 40 years later, what expert knowledge of navigation and seamanship he has. Sailing back with him from Galway to Harwich I appreciated the enormous amount of planning and detailed care which must have meant plenty of apposite suggestions from Nancy. Much experience and responsibility were displayed in that voyage out and back, in his 31ft 'Lal', so named after a woman who for him from childhood onwards, had always epitomised everything female and femininely beautiful, even in her nineties. The quartet played *allegretto or allegro con brio* all the way and never was there any of the dreadful heartiness and banter that can take possession of the crew of a yacht at sea. Douglas has twice circumnavigated Scotland and has described it beautifully in the *BMJ.* Now he is returned from crossing the Bay of Biscay this year we shall expect another beautiful clear seascape in words.

It is sad that many readers of the *Archives* or *Recent Advances in Paediatrics,* who do not know and may never know Douglas Gairdner, must make do with such a sketch as this. And must be resigned not to hear one of his brilliant imitations, which his friends are often treated to, in the form of lightning impromptu charades, all over in a moment, leaving his audience and himself in fits of laughter.

Special annotations

Schönlein-Henoch syndrome

This characteristic syndrome of skin, gastrointestinal, and joint disorders has fascinated many distinguished physicians. Schönlein[1] in Berlin described the association of arthritis and purpuric rash in 1832 and it was one of his former students, Eduard Henoch,[2] who nearly 40 years later described the association of gastrointestinal symptoms and a similar rash. Professor Henoch was one of the first German physicians to specialise in paediatrics. He maintained his interest in the syndrome throughout his life and, at age 90, shortly before his death he recorded the important association of serious kidney disease.[3] Although Schönlein and Henoch gave their names to its eponymous title it does seem that other distinguished physicians had noticed the condition earlier. There is an excellent description by Heberden in 1801, and another by Willan (1808) in his book on cutaneous diseases.[4, 5] At the turn of the century William Osler devoted many of his later years to study of the condition and his concept of 'anaphylactoid purpura' although confusing in some ways did draw a useful comparison between the systemic reaction of serum sickness and the illness of Schönlein-Henoch syndrome.[5] Douglas Gairdner from 'the Department of Child Health, Kings College, University of Durham' completed a paper on the syndrome in 1947 which was a worthy successor to its illustrious predecessors and in many ways it is still the most detailed and accurate description of the syndrome in the English language. His personal observations were based on only 12 cases, but the scholarship, research, and thoughtfulness with which they were presented makes it a more useful paper than many of its successors. It is a long paper, 30 pages, which is perhaps why he published it in the *Quarterly Journal of Medicine*. It might have received wider paediatric acclaim had it been published elsewhere. The description of the skin lesions is excellent and contains many of the points usually overlooked in subsequent publications, but which nevertheless are important diagnostic features, for instance, the way in which the rash apart from having the well known topographical distribution also has a predilection for areas of pressure, with 'a striking delay of from 12–24 hours . . . the skin creases beneath the sphygmomanometer cuff become outlined on the day *after* a blood pressure reading'. The rash is frequently found in bands on the skin near the top of tight socks or at the waist.[6] Gairdner emphasised the way in which the crops of rash could come and go for a very long time; one child whom he studied was still having crops 2 years after onset. His paper also contained what I think is the first description of the variation of the rash that is seen in young preschool children. They often have a more obviously urticarial rash with big weals which later may become purpuric. Oedema of the scalp and face and the dorsum of the hands and feet is common. The only feature he did not mention and which does cause some confusion is the subcutaneous bleeding that may occur almost anywhere, for instance, bleeding into the eyelids and conjunctiva or bleeding into the scrotum mimicking torsion of the testicle.

Further study of the condition has led to the realisation that a variety of other manifestations can occur with the syndrome; nose bleeds may be severe and there may be bleeding into the calf which simulates a deep vein thrombosis; convulsions, encephalopathy, facial palsy, and chorea occasionally occur.[7]

Gairdner's article drew attention to the spectrum of disease ranging from rheumatic fever through Schönlein-Henoch syndrome to polyarteritis nodosa. At the time his article was written streptococcal infection was common and serious in Britain. It is much less common now and less severe. No longer is the streptococcus the commonest antecedent of Schönlein-Henoch syndrome. A variety of infective agents and occurrences have been linked with the syndrome. They range from specific infecting organisms such as *Mycoplasma pneumoniae*[8] and varicella[9] to food allergens,[10] drugs,[11, 12] insect bites,[13] and exposure to cold.[14] The same syndrome can result from a variety of different provocations. Gairdner's suggestion of a link between polyarteritis nodosa and Schönlein-Henoch syndrome is one with which I agree. Polyarteritis nodosa is extremely rare in childhood but occurs either in the infant or, much later, in the teenage childhood. Schönlein-Henoch syndrome is not seen in infants, is most common in young children, and then becomes uncommon in teenage children and adults. It is almost as if the syndrome occurs in childhood instead of polyarteritis nodosa.

Gairdner said 'No treatment has been proved to have any effect upon the course of the illness'; sadly that remark is still true today.[6] Although there is widespread agreement that corticosteroids can have a beneficial effect on the alimentary symptoms,[15] no drug or course of management has been shown to affect the occurrence or recurrence of the disease or its progression. Gairdner, way ahead of his time, decried the use of bed rest for the condition pointing out that it did not seem to influence the course or the prognosis. (The impact on his readers of this splendid *cri de cœur* must have been lessened somewhat by a striking photograph a few pages later showing 'gross purpuric and necrotic lesions on the buttocks, the curved marks corresponding to the edge of the bed pan'.)

Blood-stained urine in a child with the syndrome was recognised by Heberden in 1801.[4] Gairdner was one of the first to suggest that the renal lesion was the most serious component of the syndrome. Nowadays it is the glomerulonephritis which is almost entirely responsible for the 1–3% mortality rate of Schönlein-Henoch syndrome. Of Gairdner's 12 patients, one died of renal failure and another 2 had chronic renal insufficiency. In recent years much information has been obtained about Schönlein-Henoch nephritis from several large surveys.[15,16,17,18,19,20] The proportion of patients reported to have renal involvement varies between 20 and 100% depending upon the criteria for 'renal involvement'. Raised red cell excretion rates in the urine have been found in all children with the syndrome[19] and an abnormal renal histological picture has been reported in children with Schönlein-Henoch syndrome who had normal urine on routine testing.[21] On routine testing between 30 and 70% will have albuminuria and microscopic haematuria and another 20–30% have macroscopic haematuria. Although the renal illness may be most severe in the early stages of the disease a remarkable degree of recovery is possible. Those who have merely microscopic haematuria are likely to be completely normal 10 years later. The large group who have symptomless haematuria and proteinuria on the whole do well although up to 20% may develop permanent renal damage. The small number of children who have acute nephritic syndrome and a nephrotic syndrome early in the course of the illness are those who have the most serious disease. Up to half of them subsequently develop renal insufficiency, but even for that group nearly half appear in good health with reasonable renal function 10 years later.[22,23] The pathology of the renal lesion is well studied and described but does not as yet shed much light on the aetiology.[7,24] Apart from the diffuse mesangial proliferation with pronounced focal variation that is visible on light microscopy, the outstanding finding is IgA deposition in the glomerular mesangium and also occasionally spread along the basement membrane in severe cases.[25] Its similarity to the immunofluorescent appearance of Berger's disease (clinically one of the varieties of 'recurrent haematuria of childhood') raises the question whether Berger's disease is a type of Schönlein-Henoch syndrome; after all we frequently diagnose the syndrome in the absence of involvement of joints, gut, or kidneys, but we never diagnose it in the absence of skin involvement because that is the pathognomic sign. If we had a reliable test for the syndrome we might be diagnosing it in many children who did not have the characteristic rash. Perhaps IgA deposition in the glomerulus and also in blood vessels of the skin is the most important feature.

Schönlein-Henoch nephritis accounts for about 15% of children who are put on dialysis in Europe because of end-stage renal failure. It is important that either prevention or effective treatment is found. So far there is no evidence that any drug affects the course of the renal lesion although there is a shortage of adequately controlled trials and the results of the trial of cyclophosphamide by the International Study of Kidney Disease in Childhood are awaited with interest.

The prevention and management of Schönlein-Henoch syndrome has not advanced as far as Douglas Gairdner must have hoped when he wrote his important paper in 1947. However, it is worth remembering that Sir William Osler published his most useful contribution on the syndrome after his retirement, and that Henoch who was responsible for clearly defining the renal involvement that accompanied the syndrome published that paper in his 90th year. At that rate I shall expect the definitive paper on the cause and prevention of Schönlein-Henoch syndrome to be written by Douglas Gairdner somewhere around the year 2005, and trust that he will publish it in the *Archives of Disease in Childhood* and not in the *Quarterly Journal of Medicine*.

Nephrotic syndrome of childhood: malaria therapy reconsidered

In 1952 Gairdner[1] and Byrne[2] independently reported that acute infection with malaria could induce a remission of what was then known as nephrosis or type-II nephritis of Ellis.[3] Gairdner was stimulated to investigate this type of treatment by the long-lasting remissions, amounting to cures, that occasionally followed measles in the nephrotic child[4], and recently he reported 'a notable case of nephrosis' illustrating the duration of this effect.[5]

In his paper in 1952, Gairdner described 4 children with nephrosis infected with *Plasmodium vivax*.[1] The case reports are interesting: 'On 12 January 1949, malarial mosquitoes were applied. . . . On 24 January malarial fever began, the temperature rising to 102°F. Next day diuresis set in and oedema began to subside rapidly, disappearing completely by 2 February'. However, albuminuria persisted, although in another child it cleared completely. The malarial attacks were terminated by mepacrine. One of the 2 children who did not respond developed renal failure and was shown at necropsy to have crescentic nephritis.

Subsequently, Gairdner and Shute collected the clinical details of the 65 children with nephrosis for whom the Malarial Reference Laboratory had supplied infected blood or mosquitoes.[6] 51 of these were considered to be cases of 'pure nephrosis', of whom 14 had a complete remission, although 4 of them subsequently relapsed and another 4 had proteinuria at follow-up. There was one death associated with malaria treatment, and 6 patients required transfusion.

These trials of malaria therapy were naturally not controlled, but nevertheless the impression is gained that in some cases there was a close temporal relationship between malarial fever and remission of the nephrotic syndrome. However, these were the years of excitement after the introduction of corticosteroid treatment for the nephrotic syndrome,[7] and even alkylating agents were looming on the horizon[8] so that a possible therapeutic effect of malaria was not pursued. Malaria therapy is considered in this Annotation in the light of contemporary understanding of the immunopathogenesis of the nephrotic syndrome.

Terminology

The nephrotic syndrome consists of a disturbance of glomerular permeability resulting in albuminuria, hypoalbuminaemia, and oedema. Most children respond to treatment with corticosteroids and have only slight histological changes in the glomeruli evident on light microscopical examination. The condition was called 'lipoid nephrosis' by Munk,[9] but the term nephrosis has been attacked by Oliver[10] as etymologically meaningless, and the adjective lipoid emphasises an aspect of the disease that is of only secondary importance. Some authors refer to the condition as the 'idiopathic nephrotic syndrome', which implies an optimistic assessment of current understanding of the pathogenesis of other forms of the nephrotic syndrome. Recently the term 'minimal-change nephrotic syndrome' has been popular, but there is a certain illogicality, unfortunately common in the nosology of renal disease, in the use of a pathological term to describe a condition essentially recognised by its clinical features; in many cases a renal biopsy will not be undertaken, and the histological appearances will therefore remain a presumption. The expression 'steroid-responsive nephrotic syndrome' (SRNS) at least has the merit of focusing on the most important objective characteristic of the condition, but has the disadvantage of excluding a few otherwise similar cases which do not respond to conventional corticosteroid regimens.[11]

Immunological aspects

The pathogenesis of SRNS is not known, but it is tempting to speculate that immunological mechanisms are involved. However, critical laboratory evidence of immunopathogenesis has not been forthcoming, and in cases where immunological abnormalities are observed, it is often difficult to decide whether they are a secondary effect of the nephrotic state or an epiphenomenon of the event that precipitated the relapse rather than an integral part of the pathogenetic mechanism.

Clinical observations. A number of clinical observations have suggested an immunopathogenesis of SRNS. In the first place, relapses are often precipitated by upper respiratory infections. There is an increased incidence of atopy, particularly infantile eczema or hay fever, which was reported in 38% of the nephrotic children compared with 18% of age-matched controls,[12] and there are some well-documented cases in which relapses of the nephrotic syndrome were associated with atopic features—such as grass pollen hypersensitivity[13, 14, 15] and possibly milk allergy.[16] The condition is more common in children who have the second series tissue antigen HLA-B12.[12] The association with HLA-B12 however is weak, with a relative risk of 6·3, but has been confirmed by a further study.[17] There appears to be an increased incidence of minimal-change nephrotic syndrome in patients with Hodgkin's disease, but in only 5 of the 35 reported cases has the condition been demonstrated to respond to corticosteroids alone.[18]

Pathology. About 80% of nephrotic children referred to specialist centres respond to treatment with corticosteroids[19, 20]; of these 93% have minimal histological changes of the glomeruli evident on light microscopical examination and the others have mild mesangial proliferative lesions or focal glomerulosclerosis, although the histological frontiers of 'minimal-change' are difficult to define. 5% of children with minimal-change histology do not respond to treatment with corticosteroids, although in some of these deep focal sclerotic lesions may have been missed in superficial biopsies.

Immunofluorescence studies do not show glomerular deposition of immunoglobulins or complement components.[21, 22] However, immunofluorescent methods may not be sufficiently sensitive, and it is possible experimentally to produce fatal immune complex glomerulonephritis without detectable glomerular deposition of immunoglobulin.[23] An early report that IgE could be detected in the glomeruli of nephrotic patients[24] has not been confirmed in other studies.[25, 26]

The actual site of the filtration barrier in the glomerulus which excludes proteins of the size of albumin from the glomerular filtrate is probably the split-pore diaphragm between the epithelial foot processes[27] which has a complex electron microscopical ultrastructure in which glomerular polyanions containing sialic acid residues play an integral role.[28] Electron microscopical examination generally shows fusion of epithelial foot processes in SRNS,[29] but as similar lesions can be induced in dogs by plasma infusions sufficient to cause proteinuria,[30] and as foot-process fusion persists for several weeks after remission of proteinuria,[31] it is considered that this abnormality is a consequence rather than the cause of proteinuria. Interestingly, both the aminonucleoside puromycin[32] and polycations[33] cause foot-process fusion, and Brenner and coworkers have speculated that the primary event in the nephrotic syndrome is a loss of the glomerular polyanion structure resulting in a diminished restriction of filtration of circulating polyanions, and thus albuminuria, as well as a disturbance of the foot-process structure with fusion.[34] In this context, the report of a 6-fold increase in serum-free polyamines in nephrotic children is of interest.[35]

Immunoglobulins. The plasma concentrations of IgG, IgA, and IgM are normal in remission, but IgG and IgA decrease during relapse and IgM rises.[36] It has been suggested that IgM levels remain high in remission,[37, 38] but these observations probably result from allowing insufficient time for the effects of the previous relapse to wear off. Plasma IgE is raised in one-quarter of nephrotic children, independent of the state of relapse or remission,[12, 39, 40] and there are also raised levels of IgE antibody to Timothy grass pollen and *Dermatophagoides pteronyssinus.*

Complement. Total haemolytic complement is normal in these patients[21, 41] as is plasma C3,[42] and there is no immunoelectrophoretic evidence of C3 conversion *in vivo.*[43] Plasma C4 and Clq levels are generally found to be normal,[36, 38] although there was an earlier report of reduced plasma Clq in some patients.[44] The low plasma factor B concentration is due to urinary loss,[36] and has been considered responsible for defective opsonisation of *Escherichia coli* by nephrotic sera.[45] C3b inactivator (KAF) levels are reduced as well.[46] Immunoconglutinin (IK), an autoantibody to hidden antigenic determinants in C3 and C4 is detectable in nephrotic sera during relapse, suggesting complement activation,[41] but Mallick found a less consistent relationship between IK peaks and relapse in nephrotic patients.[38] Smith and co-workers reported that sera from SRNS children in relapse inhibited the formation of EAC-rosettes by normal human tonsillar B-lymphocytes, suggesting the presence of free or complexed C3b.[47] Taken together, the IK and EAC-rosette data suggest low grade activation of the complement system.

Immune complexes. Recently Levinsky and coworkers reported the detection of circulating immune complexes in the sera of nephrotic children in relapse by a technique dependent on the inhibition of agglutination of IgG-coated latex particles by rabbit IgM antibody to human IgG.[48] Complexes were detected in relapse and persisted for several weeks after remission; they were thought not to be an artefact of nephrotic sera as they were not detectable in congenital nephrotic patients. The complexes were of moderate size (molecular weight 2–2·5 $\times 10^6$ daltons), and interestingly did not bind Clq, suggesting that if there is complement activation, it involves the alternative pathway. Immune complexes were not however detected in the sera of minimal-change nephrotic patients by a Raji cell radioimmunoassay or by a radiolabelled Clq binding assay,[49] but it is not at all unexpected for the various methods of immune complex testing to give differing results.

Lymphocytes. The absolute number of circulating T-lymphocytes, recognised by sheep erythrocyte rosette formation, is normal in nephrotic patients, as are the numbers of the subpopulations of T-cells which bind IgM or IgG, although IgG-binding cells increase in response to corticosteroids.[50] The response of SRNS lymphocytes to phytohaemagglutinin (PHA) is poor,[51] and the response to the T-cell mitogen concanavallin-A is more depressed than the response to PHA (S. N. Chapman and G. Williams, 1979, personal communication). Moorthy and co-workers demonstrated that nephrotic sera inhibited ^{3}H-thymidine uptake by normal lymphocytes in response to PHA or allogeneic mitomycin-treated lymphocytes.[52] However these lymphocyte systems are susceptible to nonspecific influences such as anaesthesia.[53] Ooi and co-workers described lymphocytotoxins in minimal-change nephrotic sera, but in many other diseases as well.[54] Leucocyte migration inhibition by nephrotic lymphocytes exposed to a crude antigen from neonatal human kidney cortex has been demonstrated,[55] but sensitisation to glomerular basement membrane antigens is generally not detectable.[56] Eyres and co-workers have also reported that lymphocytotoxicity for epithelial cells cultured from neonatal human renal cortex is specifically associated with the minimal-change nephrotic syndrome.[57] However, lymphocytes are not evident histologically in the kidneys of nephrotic patients, and therefore it is difficult to imagine that such observations are relevant to the pathogenesis of the disorder. Lagrue and co-workers described lymphokine activity in the supernatant of nephrotic lymphocyte cultures which increased vascular permeability on intradermal injection in a guinea-pig, and proteinuria on injection into the renal artery of a rat. They presented pharmacological evidence suggesting that the lymphokine stimulated the kinin system,[58, 59, 60] and there is some evidence that the kinin system is indeed activated in nephrotic patients.[61] However, we[62] have not been able to detect the differences in vascular permeability factor between nephrotic patients and controls as reported by Lagrue and co-workers.[58, 59, 60] The data so far presented on lymphocyte function in the nephrotic syndrome are intriguing but do not yet present a coherent picture; Shalhoub's suggestion that the syndrome results from a disorder of T-cell function remains speculative.[63]

Treatment

Corticosteroids. Corticosteroid treatment of childhood nephrotic syndrome was introduced nearly 30 years ago but has not been established by controlled trial.[7] The Medical Research Council conducted a trial in adult nephrotic patients, in which it was noted that there was a trend towards a higher mortality in the prednisone-treated group compared with controls; in patients with minimal change histology the disappearance of proteinuria was more rapid on treatment, but among the controls the proteinuria had nevertheless fallen to <1 g/24 h in more than half the patients 2 years after entry into the trial.[64] The same tendency to natural recovery was evident in nephrotic children before the advent of corticosteroids.[65] However, the risks of the nephrotic state are such that it would not be justified to withhold corticosteroids for any significant length of time from a nephrotic child, and the effect of corticosteroid treatment in inducing remission is obvious enough for a controlled trial not to be now necessary or appropriate. There is, however, an appreciable need for controlled trials to evaluate different methods of administration of corticosteroids, and many of the recommendations are a normal adrenal response in maintaining remislogists differ.[66]

Two-thirds of the responders will relapse. Leisti and co-workers reported an association between early relapse and a poor cortisol response to ACTH after the first course of corticosteroids, and have demonstrated that 7·5–15 mg daily of prophylactic cortisol prevents relapse, emphasising the role of a normal adrenal response in maintaining remission.[67, 68]

Immunosuppressives. It is paradoxical that the major role of immunosuppressive agents in the treatment of the nephrotic syndrome of childhood is in that group with the least convincing evidence of immunopathogenesis—that is the corticosteroid-responders and the minimal change corticosteroid-resistant patients. Alkylating agents were first used in 1952[8] and the first report of the use of cyclophosphamide appeared 16 years ago.[69] It is well established that cyclophosphamide can prevent relapse of the corticosteroid-responsive nephrotic syndrome.[70, 71] An 8-week course of cyclophosphamide in a dosage of 3 mg/kg per 24 hours results in about 75% of patients remaining in remission for one year and 50% for 5 years.[72] Results are better in older children, but children with HLA-B12 do not fare so well.[12, 17] There is no benefit to be gained from longer courses or higher doses, but shorter courses are less effective.[73, 74, 75] Cyclophosphamide is an immuno-

UNIVERSITY LIBRARY COLL

suppressive drug acting principally on B-cells,[76] but there is no rigorous evidence to support the general assumption that its effect in SRNS is mediated by its immunosuppressive properties. Chlorambucil in a dosage rising to 0·3 mg/kg per 24 hours is as effective as cyclophosphamide in inducing a sustained remission.[77] Azathioprine is not effective in preventing relapse.[78, 79]

Malaria. In the light of this rather fragmentary evidence on the pathogenesis of SRNS, how can we view the possible effect of malaria described by Gairdner? The first explanation to be considered is that malarial fever, like measles, stimulates the pituitary-adrenal axis, and that the remissions are a consequence of this. However, this is not a very satisfying explanation: why should some infections induce remission, while others, particularly viral upper respiratory infections, characteristically precipitate a relapse?

The interaction between malaria and the immune system is complex.[80] There are the immunological consequences or side effects of the acute infection, for example, the immune-complex deposition responsible for the nephrotic syndrome in African children infected with *Plasmodium malariae*.[81] However, of greater relevance is the immunosuppressive effect of malaria. Children infected with *Plasmodium falciparum* have a diminished response to the O antigen of *Salmonella typhi*, to tetanus toxoid, and to meningococcal vaccine, but have normal cellular immune responses.[82, 83] The immune response of BALB/c mice to type-III pneumococcal polysaccharide is abolished by infection with the murine *Plasmodium yoelii*,[84] and the antibody response to sheep red cells is blunted by *Plasmodium bergei* infection without detectable effect on cellular immune responses.[85] The mechanism of this immune paresis is still a matter for discussion and may involve macrophage function, but it seems that malaria, like cyclophosphamide, has a more profound effect on B-cell than on T-cell function. It is of considerable interest that both *P. bergei* infection[86] and cyclophosphamide[87] ameliorate the nephritis accompanying the autoimmune disease of New Zealand black/white F_1 hybrid mice.

The effect of measles on the immune system is however different, and, as with corticosteroids, there is a more profound effect on T-cell function, reflected in the observation of Von Pirquet who first described depression of the tuberculin response during acute measles infection.[88] Although the theoretical immunologist would have no difficulty in constructing several hypotheses to encompass the described phenomena, we sadly agree, 25 years later, with Gairdner: 'it is tempting to speculate further on the mechanism of malaria-induced remissions; but, in view of our fundamental ignorance of the cause of nephrosis, such speculations would be nugatory'.[6]

Blood formation in infancy

It is hard to believe that 27 years have passed since the first of Douglas Gairdner's papers on this subject was published in the *Archives*.[1] Although he was later to write about other aspects of neonatal haematology—such as the postnatal plasma shift[2, 3] and the control of acidosis during exchange transfusion[4]—it is perhaps his 4 papers about red cell formation[1, 5, 6, 7] which have best stood the test of time and are still 'required references' (on both sides of the Atlantic) in any article about the physiological anaemia of the newborn or the anaemia of prematurity.

In the first paper[1] the authors described the appearance of the bone marrow in normal infants during the first 3 months of life. Each baby was selected from those whose mother, having already had a normal baby, had volunteered to take part in the project. The examination of the marrow showed a decline in erythroid activity during the first one to 2 months which paralleled the fall in haemoglobin and was accompanied by a pronounced increase in marrow lymphocytes, a finding which could be misinterpreted by the unwary observer as true red cell hypoplasia. We still do not know if these 'lymphocytes' so prominent in the marrow at the nadir of erythroid activity are all truly lymphoid cells; some of them perhaps, residing in the null (non-T, non-B) fraction are stem cells or early erythroid precursors awaiting a surge of erythropoietin to nudge them into differentiation and multiplication.

In the next two papers[5, 6] results of measurement of haemoglobin, red cell count, PCV, and reticulocytes during the first 3 months on the same group of normal term babies and in a large number of cord blood samples were reported. The relative macrocytosis of neonatal red cells, the low reticulocyte count, and the progressive decline in haemoglobin between 2 and 9 weeks were noted. The authors were not the first to make these measurements, but they related them to the changing bone marrow appearances to produce a classical description of the pattern of normal neonatal erythropoiesis. The advent of the electronic counter has made more accurate red cells counts and direct measurement of the MCV possible and the use of these techniques confirms the pattern of red cell values during the first months after birth.[8, 9] Gairdner and his colleagues attributed the changing red cell picture after birth to decreased red cell production and to the effect of body growth rather than to accelerated red cell destruction. They concluded that in the fetus and the infant, erythropoiesis was governed by the arterial oxyhaemoglobin level and that erythropoietic activity was regulated to ensure a level in the fetus and newborn of about 11 g of oxyhaemoglobin per 100 ml blood.

How do these conclusions look a quarter of a century later? It has been shown, using ^{51}Cr-labelled autologous red cells that the fall in haemoglobin is due to an actual decrease in red cell mass rather than to expansion of plasma volume.[10] The red cell of the term baby, examined in the isotope era, has a life span of about two-thirds of the adult cell;[11] that this is due to an intrinsic defect has been shown by infusion of DF^{32P}*-labelled neonatal cells into normal adults.[12] There are now substantial descriptions about the metabolic characteristics of the fetal erythrocyte which include greater glucose consumption, reduced phosphofructokinase, and increased levels of other glycolytic enzymes and greater susceptibility to oxidant injury.[13] However no relationship has been established between these metabolic abnormalities, which are not simply those of a young red cell population, and the cells' relatively short survival. In the last months of fetal life the estimated rate of red cell production is 3 to 5 times that of adult life[14] and it has been suggested that this intense erythroid activity results in formation of short-lived macrocytes, so-called stress reticulocytes.[15]

Despite this evidence of decreased red cell survival, the major factor in the postnatal decline of haemoglobin is, as Gairdner surmised, decreased red cell production. The decline in marrow erythroid activity is reflected in decreased ^{59}Fe clearance and incorporation into red cells.[16] It is now evident that red cell production is mediated through the effect of tissue oxygen tension on the output of the hormone erythropoietin.[17] The site of erythropoietin production remains controversial. Although in postnatal life it is probably the kidney, fetal erythropoietin, the production of which is independent of the mother, may be made in the liver. The main effect of erythropoietin is to stimulate committed erythroid precursor cells to differentiate to proerythroblasts.[18] Erythropoietin can be detected in the plasma of the fetus and in cord blood from the newborn infant, but levels decline rapidly after birth until between 8 and 12 weeks when its reappearance heralds the resumption of erythroid activity in the bone marrow.[19, 20] Anaemic and hypoxic infants continue to produce erythropoietin during the first weeks after birth and, as Gairdner observed, show no decline in marrow activity.

---

*DF^{32P} = di-isopropyl phosphofluoridate.

The postnatal decline in erythropoietin production and the subsequent fall in haemoglobin is therefore a physiological response to the rise in arterial oxygen saturation at birth and the resulting increase in oxygen delivery to the tissues. More slowly the left shifted haemoglobin-oxygen dissociation curve which, in the fetus, favours transfer of oxygen from the maternal to the fetal circulation, gradually shifts to the right, favouring increased oxygen delivery to the tissues without impairment of oxygen loading in the lungs. This shift of the curve is mediated by the presence of increasing amounts of adult haemoglobin with increased binding of the phosphate ester 2,3 diphosphoglycerate (23DPG). It has been calculated that at a mixed venous O_2 tension of 40 mmHg the 3-month-old infant delivers more oxygen to his tissues than a neonate despite a fall in Hb from 17·0 to 10·5 g/dl.[21]

The replacement of fetal by adult haemoglobin is a function of fetal maturity and is uninfluenced by the timing of birth. Haemoglobin A is synthesised in small amounts (5–10%) from 6 to 8 weeks' gestation, until 32–36 weeks when there is a sharp increase in the synthesis of Hb A and a decline in that of Hb F; the switch is not confined to one cell line making Hb A alone and is not restricted to either marrow or hepatic erythropoiesis.[22] The mechanism of the 'switch' remains unknown, tantalisingly, since ability to reverse the process might provide an effective treatment of disorders of β-thalassaemia and sickle cell anaemia by endowing permanent possession of 100% haemoglobin F. Homozygous hereditary persistence of fetal haemoglobin and possession of haemoglobin variants with high oxygen affinity both appear compatible with normal growth and health despite possession of a permanently left-shifted haemoglobin-oxygen dissociation curve.[23]

What of the earlier and more profound drop in haemoglobin which occurs in the preterm infant? Gairdner and his colleagues distinguished between this *early* anaemia of prematurity occurring between the 2nd and 4th months after birth and the *late* anaemia occurring after 5 to 6 months; the latter being clearly due to iron deficiency. They next addressed the problem of the early anaemia.[7] Their attention, like that of many others, was partly diverted by haematinic red herrings. Cobalt, now known to stimulate production of erythropoietin, was given to 5 premature babies and caused reticulocytosis and a rise in haemoglobin but was unacceptably toxic resulting in transient exopthalmos and goitre.

Gairdner also investigated the use of oral iron and found that giving it from the 3rd week mitigated but did not prevent the early anaemia of prematurity. It has since been shown that this anaemia is not associated with a low serum iron or raised TIBC and is not influenced by early administration of oral iron.[24] Iron stores in the preterm infant are influenced by birthweight and blood loss (particularly iatrogenic), and by feeding practices; iron is readily absorbed from breast milk and breast-fed infants attain greater iron stores than those fed artificially.[25, 26] Nevertheless the preterm baby fed on breast milk, like the artificially-fed premature baby, is at risk of developing a late anaemia due to iron deficiency unless he receives additional iron. A recent prospective study of low birthweight infants used sequential measurements of Hb, iron, and TIBC and also serum ferritin, the most sensitive index of tissue iron stores. One half of the babies received supplementary iron. The same nadir of haemoglobin was reached at 2 months in both groups; by 3 months iron stores were significantly lower in the control group and by 6 months most babies in the control group, whether breast or bottle fed, were iron deficient and anaemic.[27]

The problem of iron supplementation was compounded for a while by the vitamin E story. 12 years ago it was reported that a group of low birthweight infants developed haemolytic anaemia, thrombocytosis, and oedema associated with decreased plasma levels of vitamin E and increased sensitivity of the red cells to peroxide haemolysis.[28] A number of similar reports followed and it seemed possible that vitamin E deficiency might play a role in the anaemia of prematurity. However it is now apparent that this haemolytic anaemia is a result of highly unphysiological dietary manipulation. The lipid content of the red cell membrane reflects the lipid content of the diet and in low birthweight preterm babies fed certain proprietary milks rich in polyunsaturated fatty acids the membrane becomes a substrate at risk of peroxidation. Plasma vitamin E (antioxidant) levels are low in such babies and the addition of iron generates free radicals which initiate the process of peroxide haemolysis of the red cell membrane.[29, 30, 31] Thus the haemolytic anaemia is a multifactorial disorder of artificially-fed low birthweight premature infants receiving early iron supplements: it is therefore preventable.

Serum and red-cell folate levels are relatively high in the newborn but may fall in the preterm infant within a few weeks to levels which are low by adult standards. Despite this, megaloblastic anaemia is extremely rare and there is no evidence that folate supplementation influences the early anaemia of prematurity. It has been suggested that folate supplements should be given to very immature babies or to those who are at risk of dietary deficiency.[32] Breast feeding should obviate this risk, since plasma and red-cell folate levels in breast-fed infants are higher than in adult controls.[33] It seems therefore, that breast milk is best haematinically as in every other respect.

The early anaemia of prematurity now known to be uninfluenced by haematinics, often exacerbated by venepuncture, is, like that of the mature baby, associated with reticulocytopenia and decreased marrow activity.[7, 34] Erythropoietin, measured by bioassay, was detected in the urine of premature infants at birth but was then undetected until the haemoglobin declined to a nadir at 5 to 7 weeks. Hypoxic premature infants continued to produce erythropoietin.[35] It is claimed that radioimmunoassay is a more sensitive technique for measuring erythropoietin than bioassay, but the reliability of immunoassay is at present controversial. Erythropoietin was detected using radioimmunoassay in low concentration in the plasma of premature infants. There was a significant inverse correlation between plasma erythropoietin and haemoglobin and an even more significant inverse correlation between erythropoietin and oxygen-unloading capacity of the blood. This is hardly surprising since measurement of oxygen-unloading capacity takes account not only of the haemoglobin but also of the position of the haemoglobin-oxygen dissociation curve both of which affect oxygen delivery to the tissues. In infants with right shifted curves (that is, those who had been transfused and had relatively large amounts of adult haemoglobin) the haemoglobin fell lower before an erythropoietin response was observed.[36] These results suggest that premature infants respond appropriately to a decrease in oxygen-unloading capacity by increased erythropoietin excretion.

The reason for the earlier fall in haemoglobin in the premature baby is not entirely clear. One possible factor may be decreased red cell survival; the scanty data available suggest that red cell survival in the preterm baby is shorter than in the mature infant.[11]

Stockman and Oski have recently reviewed the present state of knowledge of the anaemia of the newborn, much of it derived from their own work. They suggest that low oxygen consumption in the preterm baby allows a more profound drop in haemoglobin before reactivation of erythropoiesis, and consider that the 'anaemia' of prematurity is compatible with adequate tissue oxygenation.[37] However, most recent work on oxygen consumption indicates that O_2 consumption is higher in the preterm baby[38, 39] than in more mature infants.

The assumption that anaemia in the preterm newborn is physiological has been challenged in a recent paper in the *Archives* in which are reported results of measurement of haemoglobin, reticulocytes, P50 (partial pressure of oxygen at which Hb is 50% saturated), and available-oxygen. The figure for 'available-oxygen' is derived from the haemoglobin concentration and P50, and is calculated to be the amount of oxygen capable of being released per dl of blood. These values were correlated with the clinical features at the nadir of the anaemia. In babies of 33 weeks' gestation the clinical features of anaemia appeared to correlate better with available oxygen than with haemoglobin or P50 values; surprisingly this correlation did not hold for more mature babies, even those of 33–34 weeks' gestation. In some babies with relatively high haemoglobin but low available oxygen who were judged clinically anaemic, symptoms of anaemia improved after transfusion.[40]

The clinical features of anaemia are as nonspecific in the infant as in the adult, but it is difficult to define a more objective way of assessing them. Simple comparisons of 'available-oxygen' in the preterm baby and the adult do not allow for the fact that cardiac output is much higher in the newborn infant than in the adult.

For the moment, rather than embarking on a policy of liberal transfusion with all its attendant dangers, we should continue to observe the generally accepted criteria[41] while trying to determine more precisely which babies may benefit from transfusion.

It is good that the *Archives*, under Douglas Gairdner's editorship, has continued to provide a forum for debate about blood formation in infancy. To argue whether anaemia is 'physiological' or not is surely a question of semantics. Recent research has at least reminded us of the importance of concentrating not only on oxygen uptake and arterial oxygenation, but also on oxygen unloading at the tissues.

I am grateful to Professor Alastair Bellingham and Dr Edmund Hey for their helpful comments.

Aetiology of hyaline membrane disease

The demonstration that the lungs from infants with hyaline membrane disease (HMD) have abnormal surface properties[1] sparked off a decade of intensive study on the structure and mechanical aspects of the lungs in this condition. Douglas Gairdner played a major role in a series of classical papers on the subject which virtually brought this era to a close. The first paper gave a detailed comparison of the different methods which can be used to evaluate the surface properties of the lung in the perinatal period.[2] The others described the cellular structure and lecithin content of the lungs from perinatal deaths, particularly from babies dying with HMD.[3, 4]

This work clearly established the sequence of structural and functional events in the lungs of infants with HMD associated with surfactant deficiency. The earliest change was shown to be an interstitial oedema with localised necrosis and desquamation of alveolar epithelial cells and absence of osmiophilic granules in the type II cells. Progressive development of hyaline membranes and the initiation of repair phenomena with return of osmiophilic granules and normal surface properties were described in detail. It was recognised that hyaline membranes could develop in some cases despite normal lung surfactant and that lack of surfactant occurs, though rarely, in the term infant. In conjunction with quantitative estimates of lung lecithin content, this provided a formidable amount of new information which complemented and amplified the work published during the preceding decade.

Changing directions in HMD research

Since that time the directions of research into the perinatal lung and HMD have altered in response to two major advances. The first of these was the demonstration by Liggins that prenatal glucocorticoid administration to fetal lambs allowed them to survive if born prematurely.[5] This has prompted widespread research into the pharmacology and endocrinology of fetal lung maturation. The use of prenatal corticosteroid administration to mature the preterm infant lung *in utero*, thus preventing the development of HMD, was subsequently introduced,[6] although relative benefits and hazards are still the subjects of arguments.[7] The second major advance was the discovery by Gluck and co-workers that infants at risk of developing HMD could be detected prenatally by measurement of lecithin/sphingomyelin ratios in fluid obtained by amniocentesis.[8] The twin possibilities of being able to diagnose and treat surfactant deficiency before birth have not unnaturally preoccupied medical research workers to the exclusion of the more fundamental questions about how and why the condition arises in particular circumstances.

In this, as in other fields of medical research, real advances are episodic and each one provokes a flurry of subsidiary activity centred on the particular area of the problem highlighted by the initial work, rather than on attempts to integrate it with all other aspects of the problem. It is justifiable to ask whether we are any closer to understanding the aetiology of HMD than we were 10 years ago.

Control of fetal lung development

The problem of the aetiology of HMD is of course just a part of the far wider problem of control of fetal lung development in general. The mammalian fetal lung develops as a hollow fluid-filled organ that must be capable of rapid transformation into an efficient air-filled gas-exchange system within minutes of birth. The human lung differs from that of other mammalian species in the ability to perform this feat at any time in the last trimester of pregnancy.

Recent work on the rabbit indicates that normal mammalian fetal lung growth requires the integration of neuromuscular and secretory activities.[9] Secretion of lung liquid appears to provide a moulding force for the developing lobule which is probably enhanced by the swings in intrathoracic pressure associated with fetal respiratory movements. There is evidence that agents such as corticosteroids which cause premature structural and biochemical maturation of the lungs may also retard their growth.[10] Diversion of substrate to surfactant production could well reduce the quantity available for cell proliferation. There may therefore be a biological advantage in the lung remaining functionally immature, provided that biochemical maturation can rapidly be induced when delivery becomes imminent. To allow efficient transition to an air-breathing state one might postulate the presence of one or more early warning systems to trigger biochemical lung maturation at the onset of labour.[11] HMD would then arise as a result of failure to activate these systems or the inability of the target tissue to respond.

Trigger mechanisms for biochemical lung maturation

It is well established that endogenous glucocorticoid production is capable of inducing the enzymes necessary for surfactant synthesis[12] and specific cortisol receptors have been demonstrated in the fetal lung.[13] The glucocorticoid mechanism may adequately explain the advanced lung maturation seen in various forms of fetal stress including infection[14] or recurrent antepartum haemorrhage.[15] Although most animal species have a surge in cortisol production near the end of pregnancy it is not yet clear how important this mechanism is for normal human fetal lung maturation.[12] Infants with congenital absence of the adrenals or anencephaly[16] may be born with lungs which show normal surface properties. It is also unclear how much of the wide variation in lung maturity at any gestational age[3, 17] can be accounted for by the variable activation of this mechanism. Are there specific pathways for triggering lung maturation by methods other than cortisol release?

There is evidence that thyroxine can promote lung maturation[18] as can pharmacological agents such as pilocarpine.[19] An additional, possibly important, pathway is the autonomic nervous system.[20] Infusion of catecholamines in lambs causes inhibition of lung liquid secretion and release of surfactant.[21, 22] It is not yet established whether surfactant synthesis is increased but it would be intellectually satisfying to have a link between removal of lung liquid and enhanced surfactant production since these would be sensible activities for the fetal lung when faced with imminent discharge into a gaseous environment.

Prolonged rupture of the membranes is associated with advanced lung maturation in the human.[23, 24] This may provide a nonspecific stress which induces lung maturation directly by the glucocorticoid mechanism, or such stress might be the result of secondary infection of the liquor. It is interesting to speculate whether the intimate relationship between the fetal airways and the amniotic fluid may allow triggering of some more direct mechanism for biochemical lung maturation after rupture of the amniotic sac.

Conclusions

The main structural and functional features of HMD associated with surfactant deficiency have been well understood for a number of years.

The problem of aetiology which remains to be resolved is what determines that a particular infant develops this condition of apparent immaturity, while another infant of considerably lower maturity does not.

It is suggested that the solution of this problem demands greater understanding of the way that the fetal respiratory system interacts with its environment and of the mechanisms which influence the balance between growth and biochemical maturation of the fetal lung.

Management of hyaline membrane disease

In 1962, Arshad Warley and Douglas Gairdner wrote 'Management of the condition must at present rest on (1) recognition of the physiological disturbances present in the individual case; and (2) correction of these disturbances, so far as this may be possible, in order that the baby can be given optimal conditions for survival during . . . a self-limited illness'.[1]

17 years later this statement still summarises perfectly the neonatologist's role in producing neurologically intact survivors from hyaline membrane disease (HMD). The great advances made in recent years in understanding the role and effect of surfacant deficiency in HMD show how both these maxims still apply in the management of the condition. The avoidance of acidaemia, hypothermia, prematurity, and overventilation of the lung, each of which diminishes lung surfacant, is of prime importance in the management of such babies today.

The management of HMD can be considered under three headings. (1) The control, and if possible the normalisation, of the blood–gases. (2) The control, and if possible the normalisation, of the biochemical and physiological abnormalities generally seen in any group of seriously ill patients in intensive care—for example, hypotension, hypothermia, electrolyte imbalances, oliguria, paralytic ileus. (3) The prevention if possible, but otherwise the control of the side effects both of the treatment and the disease—for example, patent ductus arteriosus (PDA) and bronchopulmonary dysplasia.

Control of blood–gases

At the beginning of the 1960s three important studies combined to improve the treatment for infants with HMD. Firstly, Avery and Oppenheimer,[2] in the USA, suggested that the restriction of inspired oxygen concentration to <40% in an attempt to prevent retrolental fibroplasia (RLF) resulted in a higher mortality from HMD. Cross[3] and Bolton[4] subsequently gave identical data for the UK.

Secondly, Strang and McLeish[5] and Warley and Gairdner[1] showed that the primary defect in oxygenation in HMD was due to right-to-left shunting, and not, among other things, to diffusion difficulties through the hyaline membranes, aptly described as 'eosinophilic red herrings' by Gruenwald.[6]

Thirdly, Ashton[7] showed that it was the oxygen in the blood supplying the retina, rather than the oxygen in contact with the cornea, which caused RLF.

Those paediatricians, in whose view it had always been ridiculous to restrict infants to 40% oxygen, irrespective of cyanosis and progressive vascular collapse, were therefore encouraged to go on administering sufficient oxygen to keep the baby pink and, as arterial blood–gas analysis became available, to keep his Pa_{O_2} in the normal range of 60–90 mmHg (7·98–11·97 kPa).

It was shown that it was possible safely and efficiently to monitor the Pa_{O_2} on blood drawn from an umbilical arterial catheter, without the risk of RLF, and to keep it in this range, while the baby was breathing oxygen concentrations >40% for prolonged periods of time.[8]

The management of oxygenation in babies with HMD is therefore to increase the inspired oxygen concentration enough to keep the arterial Pa_{O_2} 60–90 mmHg. Would that this was all we had to do to keep the Pa_{O_2} normal!

One-third of all babies with HMD so treated in 1968 were still dying. The main reason for death was progressive hypoxaemia and respiratory failure, and the neurological sequelae—such as intraventricular haemorrhage (IVH).[8] Better ways of oxygenating infants were needed and soon were to be provided.

It had long been apparent that breathing was hard work for infants with HMD, and that some way of helping them should be devised. In 1953, Love and Tillery[9] attempted to keep the baby's lungs expanded by attaching a towel clip around the xiphisternum and suspending it from the incubator roof by means of an elastic band. Warley and Gairdner[1] used a variation of this by suspending a weight from a stitch placed under the xiphisternum. Uncontrolled, and uncomfortable, these attempts at what was really continuous positive airways pressure (CPAP) did not achieve clinical acclaim. Yet the report of Gregory and co-workers[10] applying CPAP by endotracheal tube and head box ushered in a new mode of respiratory support for infants with HMD.

Many ways of applying CPAP have been tried but most neonatologists now prefer to use either a closely fitting face mask or nasal prongs, and only apply CPAP via an endotracheal tube when weaning the baby off intermittent positive pressure ventilation (IPPV). Head boxes and bags, and negative pressure chambers have generally been abandoned because they seriously restrict access to the baby and setting them up involves the excessive handling of the frail, ill infant.

No new technique in the treatment of HMD has so thoroughly been researched and evaluated as CPAP. There can be no doubt that it raises the Pao_2 in infants with HMD, but does this benefit the baby, or does it merely give the physician that inner glow of satisfaction that comes from achieving biochemical normality? Four controlled trials have shown slight benefit, measured in terms of survival, but this was usually restricted to infants weighing >1·5 kg[11,12,13,14] no doubt due to the fact that in these units the techniques for giving IPPV were so refined that most babies with HMD would have survived regardless of what treatment was given before receiving artificial ventilation.

More germane perhaps is whether CPAP improves the infant's chances in other ways. Theoretically it should; it improves oxygenation, makes respiration more regular,[15] and it lessens surfacant consumption.[16] Durbin and co-workers[13] showed that infants receiving CPAP before IPPV were easier to ventilate. Other studies confirmed that postponing the use of CPAP until HMD was severe, and 70–80% oxygen was required to keep blood-gases normal, resulted in a more prolonged illness that was more likely to progress to the need for IPPV.[17,18,19] However these studies, as was the case with the ones on survival, also showed there was little benefit from giving early CPAP in infants <1·5 kg, although we now think that these are the very infants who benefit most. Currently we give such infants low pressure CPAP (2–4 cmH_2O) by nasal prong if they show any sign of HMD or if they require increased inspired oxygen concentrations in the first 4–6 hours of life. In larger babies we still keep to the general rule of starting CPAP when >60% oxygen is required to keep the Pao_2 >60 mmHg.[20]

The use of CPAP can lead to complications, but these are primarily associated with the use of endotracheal tubes or devices with a tight neck seal.[21] When CPAP is applied by means of a mask or prong, the main risk is pneumothorax with an incidence of 20% in some reports. Furthermore one-third of infants requiring CPAP progress to the need for IPPV, and this figure increases to nearly 60% for infants <1·5 kg.[22] For these reasons CPAP should only be used in neonatal units where high standards of intensive care exist.

In such units there can be no doubt that CPAP has contributed significantly to the survival of infants with HMD, and while it is clearly not a panacea,[23] one can only endorse the view of Chernick[24] 'One or two controlled trials in the use of constant distending pressure in severe HMD, although daring, are welcome; many more would be foolish'.

The medical profession has recently acquired a needless obsession for changing their habits only when convinced by random controlled trials.[25] Fortunately CPAP was generally accepted before the rather dismal results of such trials were published. Few would suggest a need for a trial of IPPV in patients who were apnoeic or merely gasping; to do so would be as ludicrous as a trial of external cardiac massage in cardiac arrest! Yet trials have been done and the cynical reader will not be surprised to find that IPPV only helps particular groups of infants—the smaller ones,[26] the bigger ones,[27] or none![28] In fairness to these studies it should be noted that often ventilators were being used which were less than ideal, and that IPPV was started *before* apnoea and gasping intervened. In North America many infants are still ventilated on the indication of abnormal blood-gas values, but in Britain, influenced by Reynolds,[29] ventilation is rarely started on the basis of poor blood-gases alone.

Much research has gone into how best to ventilate infants with HMD. Reynolds[30] has summarised the current views that most infants on ventilators are optimally oxygenated at rates of 30–40/min with inspiratory:expiratory ratios of about 2:1 and using about 5 cm of positive end expiratory pressure (PEEP). If these guidelines are used, peak inflating pressures exceeding 30 cmH_2O are rarely needed.

The fact that 75–80% of infants >1·0 kg with HMD who are ventilated because they are apnoeic now survive is surely a vindication (irrespective of random controlled trials) of Donald and Lord's vision in 1953,[31] the same year that Love and Tillery[9] were suspending babies from incubator roofs with elastic bands, that some form of artificial ventilation would enormously improve the chances of survival for these infants.

With CPAP or IPPV it is generally possible to keep most infants with HMD oxygenated. If this fails two other techniques have been advocated. Two reports showed a better survival rate in low birthweight infants with HMD after exchange transfusion with fresh adult blood which increased the P50 of the infant's blood.[32,33] However this has not been confirmed by others,[34] and so the technique has not generally been used. More recently the use of intravenous or intra-arterial tolazoline was shown to improve Pao_2 in infants with severe hypoxaemia from RDS.[35]

Comparatively little attention has been given to the control of CO_2, although as long ago as 1961 it was suggested that this might be a factor in the genesis of IVH.[5] Other than when weaning infants off IPPV it is unusual, in my experience, to see $Paco_2$ values >80 mmHg (>10·64 kPa), and it has long been my practice to ignore CO_2 retention if the other blood–gases are satisfactory, particularly in infants with chronic lung disease. However, the neonatal brain blood flow does increase with increased $Paco_2$,[36] and if this is combined with loss, after asphyxia, of autoregulation of cerebral blood flow to changes in blood pressure[37] it is easy to see how the coexistence of hypercapnia, asphyxia, and pronounced changes in blood pressure, which is not uncommon in HMD, could predispose to IVH. In the future perhaps more attention will be paid to keeping the CO_2 under control.

While comparatively little has been written about controlling respiratory acidosis, much has been written about controlling metabolic acidaemia. Four facts need to be remembered when discussing intravenous base therapy in the newborn. (1) With birth asphyxia, the administration of base expedites the onset of breathing and lessens the risk of brain damage.[38,39] (2) The heart works less well when bathed in acid,[40] and the fall in cardiac output thus induced has many secondary effects. (3) Surfacant synthesis turns off at pH <7·25.[41] (4) Metabolic acidaemia after the first hour of life can be lessened if not stopped by meticulous attention to maintenance of blood volume, oxygenation, and renal function.

Infusing alkali can be harmful. THAM causes apnoea,[42] while bicarbonate causes alarming surges in osmolality and blood volume,[43] and if infused to excess may induce IVH.[44] However rational use of base has not been associated with IVH.[45, 46, 47, 48] The studies implicating bicarbonate treatment in the genesis of IVH have never adequately tackled the possibility that sicker babies, more prone to surges in cerebral blood flow through damaged capillaries, are more likely to have received bicarbonate. Other studies merely confuse the issue—for example by combining IVH with other types of intracranial haemorrhage, such as subdurals which clearly have a different aetiology,[49] or by stating that it is pointless giving bicarbonate in a closed system such as RDS.[50] Clearly it is not.[43]

Routine infusions or bolus injections of base to *all* infants at risk from, or suffering from, mild degrees of acidaemia have been shown to be of no benefit in random controlled trials. Indeed one would hardly expect them to be.[47,51,52,53] There is much information on when, how, and to whom base should not be given. This must be heeded, but it should not detract from the use of bicarbonate in babies with acidaemia >5–10 mmol/l. Since Usher's first study[54] it has been apparent that administration of bicarbonate given at rates <1 mmol/min to carefully selected babies who are acidaemic improves their chances of survival.[55,56]

Control of other physiological abnormalities

Temperature. It has been known since the studies of Blackfan and Yaglou[57] that maintenance of the infant's body temperature was an important component of keeping him alive, and the extensive studies by Hey[58] gave us the basic information needed to keep his core temperature normal. In infants hypoxic with HMD, who are therefore unable to sustain their body temperatures by brown fat metabolism,[59] it is extremely important to regulate the environmental temperature, as surfacant synthesis and function are compromised if the body temperature falls below 35°C.[60,61]

Haematocrit (packed cell volume) and blood pressure. Infants with HMD are more hypotensive and have lower packed cell volumes than unaffected infants, and particularly low values are found in fatal cases.[62,63,64,65] There is no evidence from controlled trials that transfusion to correct anaemia or hypotension, or both, increases the chance of survival, but there is a plethora of clinical experience showing that hypotensive anaemic neonates improve (assessed by improved tissue perfusion and a rising Pao_2) when transfusion is given. Indeed, I always feel embarrassed when discussing the transfusion habits of neonatologists with other physicians as they become slightly patronising when told that we require evidence from controlled trials to justify transfusing a patient who has symptoms of hypovolaemia and a blood pressure half normal.

On the basis of the study of Robinson and co-workers[66] it would seem reasonable to transfuse sick neonates until a systolic blood pressure of about 35 mmHg is attained. Haematocrit values in excess of 40% should also be sustained. This is particularly true for babies being given IPPV plus PEEP for whom the maintenance of an adequate blood volume is essential.[67]

Infection. No one can like the concept of prophylactic antibiotics less than I do. Yet the mortality associated with unrecognised and virtually unrecognisable group B streptococcal sepsis masquerading as HMD immediately after birth is imposing the need to give all dyspnoeic infants a course of benzyl pencillin for at least 48 hours until cultures are known to be negative, unless some clearly noninfectious condition, like pneumothorax or congenital malformation, is responsible for the dyspnoea.[68,69]

Analysis of our data shows that 90% of infants were given antibiotics, either before or shortly after IPPV was begun[22] usually because it was not possible to exclude infection as being the cause for the deterioration which had necessitated the introduction of IPPV.

Feeding. We have I believe, become obsessed with getting food into babies to the point of it becoming harmful. Sick infants have an ileus[70] and it is therefore most unlikely that orally-administered milk will be absorbed. Unpublished analysis of our data showed this to be true. Furthermore feeding causes apnoea and reduces the Pa_{O_2}.[71] It also obstructs the nostrils[72] and can introduce germs into the bowel by way of the nasogastric tube.[73] For all these reasons infants with HMD requiring more than 40-50% oxygen or ventilatory assistance should not be fed, nor should they have nasogastric tubes passed for the first 24 to 48 hours. However the very small sick infant will have low caloric reserves that will sustain him for only a few days. For 3 or 4 days he can be given intravenous glucose electrolyte solutions, by which time even if he is on a ventilator having initially been very ill he may show signs of bowel activity—bowel sounds or meconium passage. In such infants, and those recovering from HMD, a nasogastric tube can be passed and milk feeding started, but checks should always be made to ensure that the milk is not pooling in the stomach. In infants who are recovering, oral feeding usually proceeds satisfactorily, but some infants still on IPPV will not tolerate oral feeding, and intravenous feeding should then be begun.

Monitoring. Improved monitoring of the infant during his illness has contributed to the rising survival rate in infants with HMD. Regular blood-gas analysis was established over a decade ago,[8] but within the last few years the use of continuous Pa_{O_2} catheters has stressed the fact that even 3- or 4-hourly sampling of blood-gases gives very poor information about the swings and variations in the infant's oxygenation.[74] Continuous Pa_{O_2} monitoring should now be part of the care for all infants with HMD. Furthermore since access to the arterial tree is required for blood pressure monitoring, pH and Pa_{O_2} analysis, and for biochemical and haematological measurements, I believe that arterial catheterisation remains the procedure of choice for blood-gas monitoring in sick neonates despite the promising results of transcutaneous P_{O_2} monitoring.[75] Although frequent complications of umbilical artery catheters continue to be reported from the USA this is at complete variance with my own experience both currently and in the past.[76]

The presence of an indwelling arterial catheter enables one to monitor the neonate's oxygen and BP continuously, Pa_{CO_2}, pH, and PCV 3 or 4 times a day, and electrolytes and calcium daily or twice daily as indicated, without breaking that most crucial law of neonatal intensive care—minimal handling. Furthermore the use of continuous Pa_{O_2} catheters has reinforced this law since catheters show the large and potentially damaging falls in Pa_{O_2} which follow even minor interventions.[77] Additionally, ECG and inspired oxygen concentrations should be monitored continuously and some form of apnoea monitoring device must be used, all in ways that give the maximum of information with the least interference to the baby.

The nursing staff by their constant observation and care of the infant, aided by the electronic devices, should be able to detect any minor deterioration in the infant's condition in time for prompt and efficient correction.

Treatment of side effects and associated disorders. With these standards of care the mortality rate from HMD is now about 10%[78] but new problems have appeared. The incidence of PDA[79,80] and necrotising enterocolitis (NEC)[81] in infants with HMD has become a serious matter in the USA although they seem to be less common in the UK. Is there perhaps some factor that links this with their high incidence of umbilical artery occlusions? Certainly, gut hypoperfusion—perhaps induced by an indwelling catheter—is a factor in the aetiology of NEC, and excessive fluid through a catheter may cause PDA.[82]

However out of adversity, some good does come, since the treatment of PDA with prostaglandin synthetase inhibitors[80] must count among the most exciting developments of the decade in neonatal cardiology.

Bronchopulmonary dysplasia (BPD) is a persisting problem on both sides of the Atlantic. Although this was initially attributed to oxygen toxicity[83] this explanation has always seemed naive, as the striking feature identifying cases of BPD was that such babies had received high pressure positive pressure ventilation, and babies have breathed high oxygen concentrations for prolonged periods of time in the past without developing this disease. Reynolds and Taghizadeh[84] showed that in infants with HMD, ventilation designed to lessen the applied pressures reduced the chance of the condition, irrespective of the oxygen concentration, and Stocks and Godfrey[85] showed that persisting abnormalities of respiratory mechanics on such infants are more a function of IPPV than of oxygen therapy. BPD may be minimised by early use of CPAP to lessen the pressures necessary should IPPV subsequently be required.[13]

Conclusion

It is a platitude that prevention is better than cure. Nevertheless it must be said that despite these great improvements in neonatal intensive care it behoves paediatricians to strive to ensure that fewer babies will need to benefit from them.

With better socioeconomic conditions and a higher standard of both general education and antenatal tuition, it is to be hoped that premature labour producing infants at risk from HMD will not only become a rarity but, if it should occur, will be recognised by the mother early enough for newer and more effective tocolytic agents to be administered. These will either prevent delivery or delay it long enough for effective and safe drugs to be used as surfacant inducers, rather than the corticosteroids, heroin, or aminophylline used at present. For the neonate, so lost to all sense of medical decency and decorum to be born without adequate pulmonary surfacant it may soon be possible to give him some.[86]

HMD will become rare but the techniques of management to which Douglas Gairdner and his department in Cambridge contributed so much during the last 20 years, must not be forgotten so that small sick babies with this and other conditions will continue to benefit from high standards of neonatal intensive care.

Fat in the newborn

In 1972 I received the improbable message that Douglas Gairdner wanted my advice. Our only previous contact had been on editorial matters, with me in the supplicant role, although I must nearly have met him in a different supplicant role while I waited for his niece to emerge from 19 Adams Road in March 1959. But it was far from clear to me what a research fellow had to offer him. Nevertheless, the request was pursued, he really did seem to want to see me and, what was more, it was the mountain that was going to do the moving.

Eventually he arrived at the Institute of Child Health bursting with the youthful vigour most of us never had, brandishing an Ogden's tobacco tin full of stubby little needles, a sight odd enough for any narcotic investigator. It was these that were the cause of his problem because his latest research interest, which had to do with body fat, was being frustrated by his inability to obtain samples of adipose tissue from little babies through these fine needles. Being the man he is, he had sought help from the literature and may well be the only reader of my MD thesis in the Cambridge University library. At all events I was able to give him some of my 3-inch FG 12 Bell and Croyden specials and, needless to say, he never looked back.

Between 1975 and 1977 Douglas published 3 papers on body fat in infancy.[1,2,3] The first and the last, respectively on the composition of body fat in infants and on the assessment of total body fat, were incidental to the most important of this triad, which was entitled 'Size of adipose cells in infancy'. At the time the number of infants that had been studied was extremely small. Data were available on older children, but information on the earliest and perhaps most important part of the adipose cell size and number story was lacking. Douglas's contribution focused on cell size, which is what one actually observes and measures, and that, as will be seen, was a seminal influence.

Natural history of adipose cell development

Fat cells become recognisable in the human fetus only in the last trimester of pregnancy but there are few data on cell size in preterm infants and Douglas's are probably the best. At between 25 and 30 weeks of gestation the mean adipose cell diameter is between 30 and 50 μm and this increases to 50 to 80 μm by term[2]. Site-to-site differences were apparent from the earliest time of sampling and gluteal samples regularly contained bigger fat cells than samples taken from the abdominal wall. This discrepancy increases as children get bigger so that the site from which adipose cells are taken is of considerable importance.[4]

During the first year of life adipose cell diameter continues to increase and by one year of age gluteal fat cells are about 100 μm in diameter.[5] As Douglas presciently remarked in a 'strictly tentative conclusion', the increase in body fat in the first year of life seems to be largely accounted for by a 5-fold increase in adipose cell volume.[6] Fat cell number does not change during this time in normal children and fat cell size does not change afterwards, so that by 18 months the gluteal fat cell diameter is the same as in normal adults.[7] It is now generally agreed that growth of body fat in normal persons is accommodated by increases in the size of fat cells during infancy and by increases in their numbers afterwards.

While it has been known for some time that fat cells once acquired cannot be lost, the idea that new fat cells can be formed at any time is a relatively new one[8,9] but one which is becoming increasingly clear.[10] The fact that really huge fat cells are not found in the very obese adult strongly suggests that there is a maximum fat cell size, and that when this size is reached, adipose cell replication begins.[11] The postulated critical size could change with age but the concept of size being the trigger to cell replication rather nicely explains the observations made on adipose cell numbers in normal infants described above and in pathological situations later in childhood and adult life.[12]

Changes in skinfold thickness and body fat with age

Many authors have been intrigued by the rapidity of the increase in skinfold thicknesses in infancy because it is so odd that suddenly at one year of age they stop increasing and indeed decrease in normal subjects. Surprisingly, it was not until 1973 that some data became available in England[13] which were incorporated into standard charts,[14] although Sweden was well ahead in this field.[15] Values at birth[16] are of little value as an indication of maturity,[17] but the description of their increase is now fairly well established for our population. It is worth pointing out that what applies in one country may not necessarily apply elsewhere; the pattern is quite different in Berlin, for example,[18] and comparisons can be made only with great caution.

As an isolated measurement, skinfold thickness is of limited value, but to translate skinfold measurements into terms of total body fat is a useful exercise clinically. This has been done in adults[19] and now that accurate methods for determining body fat are becoming available there are indications that skinfold thicknesses more accurately measure body fat in adults than do measures of body density.[20] In children the methodological problems of densitometry are considerable: heavy water[21] and ^{40}K[7] have been used as references for the calculation of lean body mass against which to compare skinfold thicknesses, but neither method is very satisfactory because there is so little evidence about the water and potassium content of the lean body mass in children.

In infants, whom we knew to be wetter, extrapolation from childhood values may give very dubious results, so Dauncey *et al.* used a geometrical method of calculating body fatness in infants.[3] Their formula stands up well to refined techniques of measuring body fatness, such as using xenon.[22] For practical purposes we can assume that a combination of skinfold thickness measurements gives a good indication of body fatness in infants[23] and I do not think that any serious study on nutrition in children in 1979 can afford to omit the measurement of skinfold thickness. Weight and weight-for-height indices are indirect measurements of nutritional status and are unreliable as indicators of body fatness in children[24,25] and adults.[20,26,27] We would be better without them.

Determinants of body fatness in infancy

Knowledge about the determinants of fatness is sparse both in children and adults. One of the classical ways of looking at genetic and environmental contributions to the determination of a characteristic is to compare monozygotic with dizygotic twins, but it seems likely that in body fatness this model has served us badly. Studies of both normal[28] and obese[29] twins have suggested a strong genetic contribution to body fatness, but placing reliability upon differences between twins depends on monozygotic and dizygotic twins being treated alike. If like-twins are treated more alike just because they look alike, a spuriously high correlation will be generated between them and the reverse could apply to dizygotic twins. There is evidence to suggest that identical twin pairs share more environmental factors in common than non-identical twins.[30,31] This has almost certainly affected the calculations on determinants of body fat. Hawk and Brook showed that siblings resemble each other hardly at all, while monozygotic twins resemble each other closely, and dizygotic twins are intermediate.[32] Neither we, nor Mueller and Titcombe found midparent-offspring correlations to be higher than individual parent-offspring correlations, which one would certainly expect in a genetically-determined characteristic.[33] At the time of writing the balance of evidence suggests that body fatness is largely determined by environmental factors.

These data are extremely hard to obtain and are not yet available for infants. The fact that fatter mothers have fatter babies[34] would fit with any theory of determination of body fatness and I am inclined to think that what Hawk and Brook showed for adults is likely to apply in infancy.[32]

Implications

With body fatness contributing significantly to the major risk factors for arteriosclerosis (hypertension, reduced glucose tolerance, carbohydrate induced hyperlipidaemia, lack of exercise), although it is not now itself considered a risk factor,[35] much interest has arisen about whether body fatness tracks. Do fat babies stay fat? Are the seeds of adult fatness sown in childhood?

It has been difficult to answer such questions, not least because people will weigh babies rather than measure how fat they are. This is bound to cause problems, since weight is mainly determined by height and overfeeding before weaning increases height.[36] I accept that babies whose weights reach the 90th centile during the first 6 months may have an increased risk of obesity later[37] and that famine in infancy may 'protect' against obesity,[38] but to argue from these huge retrospective studies that weight gain in infancy is the major determinant of body fatness in childhood is not supported by the facts obtained from measurements of skinfold thickness.[39] Nor do our recent data suggest that body fatness tracks reliably into adult life either for individuals of normal fatness or for those whose skinfold thicknesses in childhood were above the 75th centile.[40]

It is important to note that a number of skinfolds need to be measured to express opinions about changes in body fatness over a number of years, because fat distribution changes markedly with advancing age as the Table shows. A combination of skinfold thicknesses gives the best indication of body fatness[19] and the least between-observer error.[41,42]

Our family data support the idea that body fatness is largely environmentally determined at all

Table *Percentage increases in skinfold thickness with age (6–70 years)*

	Males	*Females*
Triceps	50	150
Biceps	25	66
Subscapular	250	233
Suprailiac	400	220

Data from Hawk (1978).[31]

ages and our longitudinal data suggest that some individuals carry with them into adult life the habits of their childhood, while others, left to their own devices, do not.

Conclusion

Body fat appears in infants through the accumulation of fat in already existing fat cells. Overfeeding causes fat cell hypertrophy which is probably the trigger for fat cell replication at any time of life. Some periods of rapid change could be more sensitive in this respect than others. Once formed, fat cells persist, but neither their size nor their number has been shown to determine levels of fatness. Fatness in adults and children appears to be largely environmentally determined. Evidence that childhood skinfold thicknesses predict well from values in infancy or adult values from childhood ones is lacking. Obesity is bad for adults and children, but greatness cannot be said to be thrust upon them.

Know the normal, or else . . .

Most babies are born in working order, and Douglas Gairdner,[1] writing about the not so private part of the new boy, in his classical and famous paper entitled 'The fate of the foreskin', described the normal separation of the foreskin from the glans, the age at which the separation normally occurs, and the undesirability of trying forcibly to retract the foreskin, at least in the first 3 years. But there are still many doctors and nurses who tell mothers that they must try to pull the foreskin back, causing pain while risking the development of paraphimosis, and clinic doctors who describe 'the redundant foreskin' or a 'pinhole meatus'. There are still many doctors who, not knowing the normal, cause defenceless boys to be circumcised. Douglas Gairdner mentioned the meatal ulcer as one of the untoward results of circumcision: Denis Browne added many others seen by him—such as urethral fistula and strange cosmetic results.[2] Now Annunziato and Goldblum add the staphylococcal scalded skin syndrome,[3] and Sussman *et al.* the Fournier's syndrome of gangrene of the genitalia.[4]

Miller *et al.* drew attention to another 'sequel' by the 4th birthday; boys who had been circumcised were at least 7 times more likely to have their tonsils removed than were the uncircumcised.[5] The Defence Organisations in Britain recently had to pay £18 000 in settlement for a circumcision which led to gangrene of the tip of the penis: and in the USA, where a higher price is placed on the organ, a settlement of approximately $3 million had to be made for a similar disaster. Kaplan in his 33-page review, having remarked that circumcision is the most common operation on males in USA, and that the cost of newborn circumcision there is calculated at $59 544 000 a year, devoted 16 pages to complications of the operation.[6]

Morgan, probably taking his cue from Douglas Gairdner, wrote two papers on the subject of circumcision—'The rape of the phallus', and 'Penile plunder', again emphasising some consequences of not knowing the normal.[7, 8]

Children can suffer much harm at the hands of doctors who do not know the normal, and the normal variations which do not require treatment. One has seen young babies operated on for tongue tie, or cysts of the gum or palate, which disappear if left alone. One sees older infants operated on for a lipoma in the sole of the foot, for which treatment is unnecessary. Although watering of the eye resulting from incomplete opening of the nasolacrimal duct almost always cures itself without probing, there are still some who attempt this. Müller *et al.* showed that the bends in the lower part of the tear duct make it impossible for a probe to penetrate Hasner's membrane so that probing inevitably produces a false passage; they recommend syringing if anything has to be done, but they state that the duct can open spontaneously as late as the 2nd year.[9] Probing requires a general anaesthetic, and I know of a death which resulted. One hears of operations for toeing in, toeing out, curly toes, flat feet, knock knee, or bow legs, and in none is treatment generally required.[10, 11] A physician's ignorance of the normal plays into the hands of over-active surgeons.

When Mueler inspected the tonsils of 640 children aged 5 to 16 and reported that only 14% had 'normal' tonsils,[12] one wonders how the word normal should be defined. Denzer and Felshin described a study in New York in which tonsils of 1000 11-year-old children were investigated: 610 of children were found to have had the tonsils removed, and when the remaining 390 were referred to ENT specialists, all but 65 of them were advised to have the tonsils removed because they were 'abnormal'.[13]

The observation of a click in the hip of the newborn causes innumerable babies to be placed in 'double nappies', despite the current opinion that the 'click' is of no significance and that double nappies are a useless form of treatment.[14] According to Ramsey, Ortolani wrote that the important 'clunk' or 'jerk' is never found under age 3 months, an opinion with which Ramsey agreed.

One has seen many incorrect diagnoses of cerebral palsy because of failure to recognise normal variations in muscle tone, in the briskness of tendon jerks, or in motor development. This can be a tragedy for the child: I have seen a normal child rejected for adoption on the grounds that he was spastic. I am convinced that only an expert should be allowed to cause a child's adoption to be rejected on the grounds of some abnormality. One has seen children subjected to prolonged physiotherapy at enormous inconvenience to the parents and expense to the NHS for supposed cerebral palsy, when in fact there was no abnormality.

A bizarre feature of paediatrics in some quarters is the widespread application of the terms 'brain-damaged', or 'minimal brain dysfunction' (or 'damage'), or the 'hyperkinetic syndrome', to children whose behaviour disturbs adults. Schmitt wrote that over 100 symptoms have been put into this ragbag diagnosis.[15] Rutter,[16] and Sandberg *et al.*[17] showed that there is no justification for designating these symptoms a 'syndrome'. There is much to be said for making a diagnosis which no one can prove or disprove, as long as it does no harm. Doctors feel better when they have put a name to a condition, whether or not the name means anything, but the term 'brain damaged' is harmful to the child because it 'labels' him, with the risk that teachers will treat him differently from others, with the self-fulfilling prophecy effect. In certain countries these labelled children are given daily stimulant pills with side effects which include stunting of growth, while the child is started on the pill-taking pill-dependent track which may affect him for life. Furthermore, parents are greatly distressed when told that their child is 'brain-damaged'. No one can deny that an occasional child is truly 'overactive': but the diagnosis of the hyperkinetic syndrome, or slight brain damage, is often applied to normal children who have got nothing wrong with them (and need no treatment for taking after one or other of their parents). Many do not realise that there is no psychological or other test which proves that a child's symptoms are due to brain-damage.

Failure to know what is normal, or a mere normal variation not requiring treatment, may cause serious parental anxiety in many other ways. I have seen numerous normal children who had been said to be mentally defective, spastic, or hydrocephalic. I have seen mothers who were told that their normal babies were spastic because they were 'not showing the right responses', or had a 'persistent primitive reflex'. The mother of a 6-month-old baby was told by a health visitor that her child's head was 'too small'. The health visitor had failed to relate the size of the head to the size of the baby and, in fact, the baby was normal with an unusually high developmental quotient. A health visitor stated that she 'failed' 40% of babies at the 6-month assessment, and I found that she had told the mothers that their babies had failed. On the Continent I heard that at the 8-month assessment babies were being referred in considerable numbers to psychiatrists, psychologists, neurologists and others, and that in the 4-year-old assessment 40% were thought to be retarded. Many are insensitive to the psychological implications of referrals from assessment clinics: referrals for suspected defects of vision, hearing, or the hips are usually essential, but apart from those, referrals may cause much parental anxiety without any advantage to the child. Many referrals are due to failure to recognise the range of normality, often because of reliance on charts showing the centile distribution of milestones of development or physical growth. In fact one can never draw the line between normal and abnormal, and the fact that a child's milestone, weight or height, is below a certain centile by no means proves that he is abnormal. Centile charts should be used with judgement. Unless a doctor uses clinical judgement and knows the normal and normal variations, many normal children will be subjected to unnecessary investigations which may be unpleasant, even dangerous, undoubtedly costly and which will certainly cause parental anxiety.

Conclusion

As a necessary preliminary to diagnosing the abnormal, it is essential to be thoroughly conversant with the normal, with normal variations, and especially the reasons for those variations. The result of not knowing the normal brings much suffering for the child, unnecessary investigation, unnecessary medical treatment and surgical procedures, with inevitable anxiety for the parents. Douglas Gairdner's famous paper drew the attention of the world to one aspect of the normal which is still not known to many.

'The decline and fall of hospital paediatrics' 23 years after

When Douglas Gairdner predicted the imminent decline and fall of hospital paediatrics he was assuming that in a relatively affluent and competent society, for which the zymotic diseases were losing their terrors, the inpatient units that we had developed would lose their *raison d'être* once the purposes for which they had been founded had been more or less achieved.[1]

Hospitals were originally places to which the indigent poor resorted when their homes could not provide the conditions needful for their care and cure, or where they were sent either because it was thought that they were infectious and therefore dangerous to the rest of the community or because the sufferer had become a charge on the parish. It was therefore only relatively late in the development of medical services that hospitals for children were founded since it could be assumed in most cases that their best care-takers would be their own families—unless they were foundlings or orphans—and that away from their families they were likely to pine rather than to recover.

The children's hospitals grew out of the dispensaries[2] that provided rudimentary primary care for those children whose poor parents were unable to pay for the services of a physician or apothecary when it was recognised that in many cases home conditions were such as to be inimical to their recovery or rehabilitation. But as in adult medicine, hospitals provided a setting in which physicians were able first to categorise and then to study scientifically the diseases that had led to admission; and this proved to be the essential preliminary to developing measures for prevention or treatment. Usually such physicians were generalists who, while earning their living in private practice, devoted their public practice to the study of a specialty—of which paediatrics became one. Thus initially paediatrics became the study of diseases peculiar to children rather than the general medicine of childhood; and this distinction is one that has ever since bedevilled the relations between paediatrics and what has now become adult medicine.

The separate development of the children's hospitals—such as the Royal Manchester Children's Hospital and Great Ormond Street, the children's wards in the general and university hospitals, the isolation hospitals whose clientele were mainly children, and the workhouses with their infirmaries, also led to divisions in paediatric practice which we are still trying to sort out and overcome. Generally, the children's hospitals succeeded in the task of identifying and arriving at some understanding of the illnesses of childhood as they then were, and in developing a corps of children's doctors, nurses, and ancillary workers with experience in dealing with children.

Paediatrics as a separate specialty developed late; it was difficult in Britain to earn a living from private paediatric practice, and it was only after the second world war, with the establishment of the NHS and the provision of free medical care for women and children, as well as for insured workmen, that physicians with an interest in the diseases of childhood and no private income were able to devote themselves totally to paediatrics: in fact Gairdner's generation must have been the first in which physicians could make it a full-time career. These physicians inherited the facilities and traditions of the various children's hospitals and units which had been developed throughout the country and, reinforced by refugees from countries with a tradition of paediatric practice (for instance in Manchester the institutions founded by Merei and Borchardt in the 1850s), and by experience in the great American paediatric hospitals, they were able to take full advantage of the therapeutic explosion that began with the development of effective chemotherapy. Thus within a decade their wards began to empty and paediatrics became, like chest medicine, one of the specialties which could be said to have fulfilled its mission.

This was the situation when Gairdner wrote his article; and its influence was the greater because of doubts about what may be called the negative aspects of hospital care; separation from home and family, the interruption of schooling, the need for constricting discipline in a busy ward, and the possibilities for cross-infection. It was the time when Bowlby's views on separation became common knowledge, when the St Mary's home care scheme was established, and when all-day visiting, hospital schools, and ultimately, facilities for play in hospital became *de rigueur*—changes which had the important side effect of totally altering the role of children's nurses from substitute mothers into the givers of support to visiting mothers (and injections) and which may be partly responsible for our present difficulties in recruiting children's nurses.

Donald Winnicott put it very well in an unpublished letter to Robert Tod defending the new attitudes: 'I became a Physician in charge of my own Department at the Paddington Green Children's Hospital in 1923 and retired after 40 years. In the course of that time there was a gradual shift in the work of the Department from physical illness to emotional disturbance or to the psychological aspect of the personality if one uses the word psychological without specifically linking it with academic psychology.

'At the same time I had an appointment of a similar nature in the decade 1923–33 in the East End at the Queen's Hospital for Children, now Queen Elizabeth's. Here I saw a very large number of patients and was in charge of the LCC Rheumatism Clinic which dealt with rheumatic fever and chorea and concomitant heart disease.

'We also had to deal with very severe summer diarrhoea and various polio epidemics and, of course, those were the days before antibiotics so that our wards were full of children with pus in the lungs, the bones, or the meninges. Penicillin put a stop to all that and transformed physical paediatrics into something which could afford to look at the disturbances that belong to the lives of children who are physically healthy. In a way, therefore, the advances of physical paediatrics opened up the field for child psychiatry. I tried to make full use of this new development.'

Many paediatricians still in practice will be able in their mind's eye to contrast the spick and span wards of their professional childhood with their rows of tidy beds and lockers, their institutionalised inmates, and their well-organised routines with the present informality. The substitution of an endo- for an exo-skeleton does not of course necessarily imply a loss of efficiency.

But structures are not so rigid that they cannot be adapted to new circumstances, and progress in medicine is like that of the hill walker who on gaining one summit gets his first view of the next. In more or less conquering the zymotic diseases and their after effects we gave ourselves the opportunity of tackling properly a whole range of problems including those of the handicapped child, those posed by the newborn baby, and those resulting from congenital abnormalities both structural and biochemical; moreover there is still plenty of work for a short-stay hospital ward whether in terms of investigation (such as those necessary to determine the aetiology of short stature), for observation (as in cases of unwell babies at risk of sudden death), for evaluation (as in cases of suspected inflicted injury), and for treatment (as in the case of status asthmaticus, diabetic keto-acidosis, leukaemia, and intensive care). Thus 45% of the sample of children followed in the National Child Development Study were admitted to hospital by age 7 years.[3]

The number of available beds has not in fact changed greatly though recently there have hardly been enough trained nurses to man them as a result of what we must consider mistaken policies emanating from the General Nursing Council. Administrators who measure efficiency by bed occupancy and who do not understand that bed occupancy and turnover are necessarily inversely related should be made to recognise that beds in which there is no turnover will always be occupied and that to ensure a good turnover with the minimal length of stay that is best for children and no waiting, a large proportion of beds must be free at any one time. In fact maximum usage of beds depends on filling them from a waiting list with minimum delay which is incompatible with coping efficiently with a large emergency load and is a great strain on nursing staff. The available beds could however be better used if no children were nursed in nonpaediatric wards (including those in isolation hospitals), which despite Platt they still are, and if we had enough trained nurses.

Thus it did not need the application of Parkinson's Law to keep the children's wards turning over.[4] We should be less complacent about the growing need to admit children with relatively trivial illnesses from materially 'good' homes because their mothers are at work and cannot look after them; but while women continue to believe that they will get the best rather than the worst of both worlds by trying to hold down a job as well as rearing a young family, the hospital will have to back up the nursery in this way. So it is that, contrary to Gairdner's prediction, the children's units remain nearly as busy as they ever were; and we are now less worried about separation which is mitigated by short-stays and all-day visiting and where ill effects have been shown to be related as much to home as to hospital conditions: indeed some children only thrive *in* hospital.[5]

What of the future? Looking at the present work of the paediatrician, it is clear that it comprises three main activities: the out- and inpatient care of acute and chronic illness, which includes investigation as well as nursing and treatment; involvement in child care in the home and at school, and especially with the assessment and amelioration of handicap; and the sometimes intensive care of the vulnerable newborn. We also need to recognise that our patients come from the maternity hospitals and are passed on to the general hospitals and that in the case of adolescents now surviving protracted and serious illness in childhood—such as cystic fibrosis, malignant disease, inborn error, muscular dystrophy etc.—the handover may be traumatic and can expose them to danger when neither the adult physician nor the GP is experienced in the kind of care that they need.

Paediatrics has now developed to the point where most physicians dealing with adult patients acknowledge that the paediatric physician has more to offer the sick child; and in these circumstances demarcation disputes should be a thing of the past with the paediatrician dealing with those children brought to the doctor by their parents or guardian and the internists with those seeking a consultation of their own volition. Some physicians may reasonably want to share the care of certain patients with their paediatric colleagues in the children's wards; and in exchange they should perhaps offer beds and help to paediatricians whose patients have outgrown the facilities of a children's unit! It seems obvious that isolated comprehensive children's hospitals will have less to offer in the future than units sharing a campus with obstetric and general hospitals; and that it should be acknowledged that adult medicine and paediatric medicine need also to share their knowledge (each has so much to learn from the other) in caring adequately for children with advanced organ system disease. In this field one foresees the development of combined medical and surgical units run jointly by paediatricians with an interest in an organ system and organ system specialists with an interest in children. Such a children's unit would need its own building (though with link corridors to the obstetric and general hospitals sharing the site), its own ancillary staff, a children's trained nursing staff not at the beck and call of senior nursing officers on the adult side, its school, and its subdepartments of radiology and pathology. It would operate mainly as a polyclinic with only enough beds—including day beds, planned investigation beds, observation beds, and an intensive care unit—to serve its outpatient department, assessment unit, and casualty departments; and the last would in city centres provide a hospital-based primary care service run by the local GPs or department of general practice.[6] The children's unit should also house the departments of child psychiatry and paediatric surgery and, very important, anaesthetics, and be closely linked with the department of genetics. The paediatric division would provide a forum for all those in paediatric care whether at primary, secondary, or tertiary level. Such a unit might well in most cases serve an area rather than a district, especially in conurbations, as well as making its regional contribution.

Identity having been acknowledged, collaboration between equals is possible and desirable. But in certain respects we need to maintain autonomy; and we have links with obstetrics as well as with medicine, surgery, and psychiatry. As a major part of general medicine (that of childhood) we have properly remained within the College of Physicians; but if, in order to regulate our training and to give representative advice to government, we need to establish our own faculty, we could perhaps ask the adult physicians in equity to do the same. As regards the British Paediatric Association, perhaps it could revert to its original aims—modelled on those of the Association of Physicians—of sharing advances in knowledge and promoting friendship between members. But if paediatrics is to continue to thrive, we must put the service and the discipline first in our loyalties and not our institutions however venerable and famous. Douglas Gairdner was right in seeing that an era had come to an end; but it was not that of hospital paediatrics but that of isolated paediatric hospitals. The future lies in collaboration with our colleagues in other specialties as well as with the development of our own specialties, for paediatricians are essentially general physicians both by inclination and because of the nature of most of their work, which is concerned with the origins rather than the results of disease. This is where our contribution to the prevention of ill health in adult life will be important; and perhaps in that context we can look forward to the decline and fall of all hospital medicine and even of the maternity hospitals.

In common with all paediatricians, I am indebted to Douglas Gairdner for making me think about the current problems and their possible solutions. I am grateful to Dr D. H. Vaughan of the Manchester Regional Health Authority for supplying the relevant national and regional statistics, and to Mr T. Ibison, Sector Administrator, Royal Manchester Children's Hospital, for allowing me to study Mr I. T. Wood's unpublished MSc thesis 'Report on RMCH. An OR-based examination of the performance characteristics of the Royal Manchester Children's Hospital'.

Rectal administration of diazepam in solution in the acute treatment of convulsions in infants and children

Anticonvulsant effect and side effects

FINN URSIN KNUDSEN

Department of Paediatrics, Glostrup Hospital, Denmark

SUMMARY In a prospective study 44 children, aged 6 months to 5 years, admitted to hospital with febrile convulsions or epilepsy, were treated with diazepam in solution administered rectally during 59 generalised attacks. Rectal administration of diazepam was effective in the acute treatment of convulsions in 80% of cases. In 10% the treatment failed, whereas diazepam administered intravenously had prompt effect; another 10% of the convulsions were resistant to diazepam, irrespective of the route of administration. The therapeutic effect was significantly correlated with the duration of convulsions before treatment started. Early treatment (convulsions $\leqq 15$ minutes) had effect in 96%, and late treatment (convulsions >15 minutes) in 57% of cases. A total of 317 children admitted with febrile convulsions were treated prophylactically with diazepam administered rectally whenever the temperature was $\geqq 38\cdot5$°C. No case of significant respiratory depression or other serious side effects was observed. The rapid and reliable anticonvulsant effect of diazepam given rectally and the very few side effects makes this treatment a valuable alternative to IV administration in childhood.

Diazepam given intravenously is one of the best anticonvulsants available for acute use. However, during convulsions in young children IV injections are often difficult or impracticable. An alternative route, therefore, is needed. Suppositories are of limited value in emergency treatment, the therapeutic plasma concentration not being reached until after about 20 minutes (Knudsen, 1977). The anticonvulsant effect of diazepam administered IM can be unreliable because of unpredictable absorption (Dundee *et al.*, 1974).

A solution of diazepam given rectally will be absorbed rapidly and almost completely (Agurell *et al.*, 1975) and anticonvulsant plasma concentrations are obtained within less than 4 ± 1 minutes (Knudsen, 1977). However, no clinical studies are available on the value of this route of administration in the acute treatment of convulsions and on the side effects (Dulac *et al.*, 1978).

Patients and methods

The prospective study took place between 1 October 1976 and 1 October 1978, during which period 349 children with febrile convulsions and 12 with epilepsy (Table 1), aged from 6 months to 5 years, received therapeutic or prophylactic diazepam, administered rectally, while in hospital. The acute anticonvulsant effect was assessed on the basis of the therapy group and the side effects on the basis of the prophylaxis group.

Acute treatment. A total of 44 children who had convulsions on arrival in the emergency ward or who developed convulsions during admission received acute treatment with diazepam given rectally during 59 generalised attacks. The duration of the convulsion after administration of the drug was registered by means of a stop watch. If the attack had not

ceased within 5 minutes rectal treatment was repeated or the child was given diazepam intravenously. Thus, the IV route was used only when rectal administration was unsuccessful.

Prophylactic treatment. A total of 317 children admitted with febrile convulsions received prophylactic treatment with rectal diazepam when the rectal temperature was $\geqq 38\cdot5$°C. All of them were monitored clinically with a view to development of respiratory depression or other serious side effects. In 225 of the children the respiratory rate was recorded before each administration of diazepam and 10 minutes later—that is, at the time when the plasma concentration is at its highest (Knudsen, 1977).

Diazepam administration and dosage. We used a prepackage containing a 2·5 ml disposable plastic syringe, a 6 cm long plastic tube with a blunt tip, and diazepam solution (Apozepam,* 5 mg/ml diazepam, ampoules of 2 ml). The solution used was the undiluted ordinary IV preparation. Similar doses were given therapeutically and prophylactically. Children aged $\leqq 3$ years received 5–7·5 mg diazepam rectally (0·5–0·9 mg/kg per dose), children >3 years were given 7·5–10 mg diazepam rectally (0·6–0·8 mg/kg per dose). The prophylactic treatment was repeated every 8–12 hours whenever the child had a rectal temperature of 38·5°C or above (1·0–2·7 mg/kg per 24 hours). In the prophylaxis group, 57% of the children received one dose, 34% between 2 and 3, and 9% of children between 4 and 6 doses over a period of 2–3 days.

Statistical methods. The P-values were calculated using the χ^2 test or Fisher's exact test.

Results

The anticonvulsant effect of diazepam given rectally is shown in Tables 2 and 3. A total of 44 children received this treatment during 59 attacks. In 5 of these cases no effect could be expected from rectal administration, the convulsions being resistant to diazepam—that is, they did not stop even after very high doses of diazepam intravenously (2–3 mg/kg per $\leqq 20$ minutes), which was given if rectal administration was unsuccessful. In 80–87% of the remaining cases (n=54) rectal administration had a satisfactory anticonvulsant effect, defined as cessation of convulsions $\leqq$ 5 minutes or $\leqq$ 10 minutes after administration (Table 2). This group included 7 (13%) patients with recurrences within 15 minutes of the first attack, the second fit stopping $\leqq 5$ minutes after administration of another dose. The therapeutic effect was significantly correlated with duration of the attack before treatment. Early treatment had effect in 96%, and late treatment in 57% of cases ($P<0\cdot001$) (Table 3).

$>$15 minutes	28	7	20/35	(57)	
Total	35	24	43/59	(73)	

No case of clinically significant respiratory depression or other serious side effects was observed in the 317 children receiving prophylactic diazepam treatment. The respiratory rate did not change significantly ($P>0\cdot3$) on the 225 children examined, even after repeated doses of diazepam ($P>0\cdot3$). Sedation was common. In 2 patients who developed purulent meningitis during treatment the diagnosis was easily established, the stiffness in neck and back not being concealed by diazepam. In a third patient the possibility cannot be excluded that establishment of the diagnosis was delayed a few hours.

Discussion

Rectal administration of diazepam was effective in the acute treatment of convulsions in 80% of cases. In 10% the treatment failed, whereas diazepam given intravenously had prompt effect. In another 10% the convulsions were resistant to diazepam, irrespective of the route of administration (Ferngren, 1974). Early treatment was effective in 96%, and late treatment in 57% of cases. Consequently, rapid intervention must be considered a prerequisite for achieving optimal anticonvulsant effect.

---

* Specially prepared by Apothekernes laboratory, Oslo, Norway.

For ethical reasons the study did not have an untreated control group. However, the obvious correlation between treatment and cessation of convulsions indicates a significant therapeutic effect. The pronounced agreement between clinical effect and pharmacokinetic properties (Agurell *et al.*, 1975; Knudsen, 1977) leads to the same conclusion. Lack of effect of rectal administration may be due either to poor absorption in a few cases or to convulsions which respond only to very high plasma concentrations.

No serious side effects were observed, even after repeated administration which gives rise to considerable accumulation of diazepam (Greenblatt and Shader, 1974). It remains to be clarified whether diazepam, which has a pronounced relaxing effect on muscles, may conceal stiffness in neck and back.

The rapid and reliable anticonvulsant effect and the very few side effects make the rectal route of administration a valuable supplement or alternative to IV administration in infants and children. In order of priority, according to therapeutic value, the various routes of administration of diazepam would be: IV injection, rectal administration in solution, IM injection, and suppositories.

In the prophylactic treatment of febrile convulsions (Knudsen and Vestermark, 1978) diazepam in solution offers hardly any advantages over suppositories. However, with the former, using the same medication, combined prophylactic and therapeutic control of convulsions is offered. Our experience shows that most parents with children suffering from febrile convulsions are able to treat their children at home prophylactically or in cases of recurrences. All hypnotics and psychosedatives, including benzodiazepines, have a potential respiratory-depressive effect. The treatment, which gives high plasma concentrations (Knudsen, 1977), should therefore only be given at home if the parents are carefully instructed (verbally, in writing, and by means of demonstrations), and if the child's reaction to the treatment has been studied during admission to hospital, in particular if the child is treated concurrently with phenobarbitone.

Water loss from the skin of term and preterm babies

N. RUTTER AND D. HULL

Department of Child Health, University of Nottingham

SUMMARY Water loss from the skin of term and preterm babies, nursed naked in incubators under neutral thermal conditions, was measured by a method based on estimating the water vapour pressure gradient close to the skin surface. 199 sets of measurements were made on 78 babies whose gestational ages ranged from 26 to 41 weeks, during the first 4 weeks of life. Babies of 34 to 41 weeks' gestation had high water losses in the first 4 hours after birth, which then fell to low levels averaging 6 g/m^2 per hour. Babies of 30 to 33 weeks' gestation had high water losses in the first week which then fell to levels similar to those of mature babies. Babies <30 weeks' gestation had strikingly high losses, averaging 32 g/m^2 per hour in the first 4 days of life. At 2 weeks, levels were still higher than those of mature babies. Light-for-dates babies had skin water losses appropriate for their gestations. The high water losses in extremely preterm babies are probably transepidermal and the result of a thin, poorly keratinised stratum corneum. Water loss from the palms and soles was high in term babies and although low in preterm babies it rose steadily in the first 4 weeks of life. This is thought to represent the onset of emotional sweating. In terms of actual heat and water lost, skin water loss is relatively unimportant in term babies nursed naked under neutral thermal conditions. However, in babies <30 weeks' gestation, weighing <1 kg, skin water loss makes a major contribution to overall water balance. Furthermore, evaporative heat loss from the skin may exceed resting heat production. It is suggested that reduction of skin water loss in these babies may increase their chances of survival and their rates of growth.

Water loss from the skin of a newborn baby, either directly through the epidermis or from the sweat glands, may be important, firstly, as a source of heat loss and, secondly, as a major factor in overall water balance. Measurement of skin water loss from babies has been hampered in the past by the lack of a suitable method. Total insensible water loss from the skin and respiratory tract has been measured using a metabolic chamber (Hey and Katz, 1969; Zweymuller and Preining, 1970), or by measurement of weight loss (Levine *et al.*, 1930; Fanaroff *et al.*, 1972; Wu and Hodgman, 1974; Marks *et al.*, 1977). Measurements of skin water loss from isolated sites have been made using a ventilated capsule (Foster *et al.*, 1969; Cunico *et al.*, 1977). Results suggest that skin water loss is low in term babies, but that in preterm ones, whether nursed naked in standard incubators or under radiant warmers or phototherapy, losses are high.

Nilsson (1977) described a method for measuring water loss from the skin, based on estimation of water vapour pressure gradient close to the skin surface. Hammarlund *et al.* (1977) used this method to measure transepidermal water loss in term infants nursed naked in incubators under neutral thermal conditions and found that it decreased as the ambient humidity was increased. They also measured rates of evaporation from several sites in a small number of babies on the first day of life and found that while rates were high on the face and extremities, they were generally low elsewhere. We were interested in using this simple method to examine the rates of skin water loss from different parts of the body in both term and preterm infants, and to see how they changed with postnatal age.

Method

Evaporation rate (ER) of water from the skin was measured using the commerically available apparatus devised by Nilsson, the Evaporimeter EP1 (Servomed). This measures the water vapour

Department of Child Health, Medical School, Queen's Medical Centre, Nottingham
N. RUTTER, senior lecturer in child health
D. HULL, professor of child health

pressure gradient close to the skin surface which is directly proportional to ER. The method has been described in detail (Nilsson, 1977). The relative humidity sensors were calibrated by placing the probe in atmospheres of known humidity.

Measurements were made on naked babies in a standard single-walled incubator with a proportionally controlled heater (59 or 79, Vickers Medical) the air temperature of which was set close to the lower end of the thermoneutral range, according to the values reported by Hey (1971). Several very low birthweight babies in the first week of life required incubator air temperatures in excess of 36·9°C to maintain normal rectal temperatures, these temperatures being the maximum obtainable when using the incubator in the air mode. In these cases, servo-control was used, setting the abdominal skin temperatures to 36·5–36·9°C and allowing the air temperature to rise to 39°C if necessary. Measurements were made on the quiet or sleeping baby through the portholes of the incubator at least 20 minutes after any adjustment to incubator temperature. The ER from a small area of skin (approximately 1 cm^2) was measured by lightly resting the probe on the baby's skin until a stable reading was obtained. To avoid errors due to moisture on the investigator's hands, rubber gloves were worn. ER in g/m^2 per hour was measured at 18 different skin sites in all babies: forehead and cheek representing the head (21%), chest and abdomen (14%), back (13%), buttock (5%), anterior and posterior surfaces of the upper arm (8%), and lower arm (6%), palm and dorsum of the hand (5%), anterior and posterior surfaces of the thigh (11%), and lower leg (10%), and the sole and dorsum of the foot (7%). The figures in brackets represent the percentage of the total surface area contributed by the various sites in newborn babies (Lund and Browder, 1944).

The rectal temperature was measured in term babies with a mercury thermometer inserted approximately 4 cm into the rectum and in preterm babies with a thermocouple probe inserted approximately 8 cm into the baby's rectum. The relative humidity within the incubator was not controlled but was measured with the Evaporimeter probe and recorded. The incubator air temperature was measured with a thermocouple placed in the centre of the incubator. Skin temperature was measured by a thermocouple lightly taped to the upper abdomen. The gestational age of the baby was calculated in completed weeks of pregnancy from the first day of the mother's last menstrual period. In addition, in the preterm babies (37 weeks' gestation or less) a gestational assessment was carried out using a scoring system based on external characteristics (Farr *et al.*, 1966). Results were not included if there was a wide discrepancy between the assessed gestational age and that based on the mother's menstrual data. Babies were judged either appropriate or light-for-dates using the 10th centile on the charts of Babson *et al.* (1970) and Thomson *et al.* (1968).

Subjects

The babies were divided into four groups according to gestational age.

Group 1 (38–41 weeks). 57 sets of measurements were made on 36 healthy, term babies, all appropriate for dates, aged from 2 hours to 10 days. Mean birthweight was 3·31 kg (range 2·60–4·36).

Group 2 (34–37 weeks). 29 sets of measurements were made on 16 healthy babies, aged from 2 hours to 21 days. Nine babies were light-for-dates. Mean birthweight was 2·08 kg (range 1·07–2·90).

Group 3 (30–33 weeks). 65 sets of measurements were made on 16 healthy babies, aged from 2 hours to 27 days. Four babies were light-for-dates. Mean birthweight was 1·43 kg (range 1·01–2·20).

Group 4 (<30 weeks). 48 sets of measurements were made on 10 babies, aged from one hour to 25 days. All were appropriate for dates. Eight of the 10 babies were unwell with either recurrent apnoea or respiratory distress syndrome during at least one of the sets of measurements. They were receiving oxygen and intravenous fluids. Six babies were receiving intermittent positive pressure ventilation when studied. Six of the 10 babies died. Mean birthweight was 0·89 kg (range 0·66–1·34). Gestational ages ranged from 26 to 29 weeks.

Results

The babies were studied at ambient temperatures judged to be close to the lower end of the thermoneutral range (Table 1). Room air temperature varied between 25 and 30° C and thus the operative environmental temperatures, allowing for radiant heat exchanges, were probably about 1°C less than the actual incubator air temperatures (Hey and Mount, 1966). The mean abdominal skin and rectal temperatures of babies below 30 weeks' gestation in the first week of life were lower than those of more mature infants in spite of high incubator air temperatures and, in many instances, the baby's surface and rectal temperatures were below that of the surrounding air. Relative humidity varied between 27 and 63% and mean values in each group of babies were similar.

Overall skin water loss. An overall water loss, representative of the loss from the baby's skin as a whole, was obtained by multiplying each of the 18 measurements of ER by the percentage contribution that the measurement site made to total surface area and then adding these together. Results were examined for each group of babies.

Group 1 (Fig. 1)

Water losses in this group were low. Measurements made in the first 4 hours averaged 10·5 g/m² per hour but after this values fell. Average skin water loss after the first 4 hours was 5·9 ± 1·3 g/m² per hour (mean ± SD).

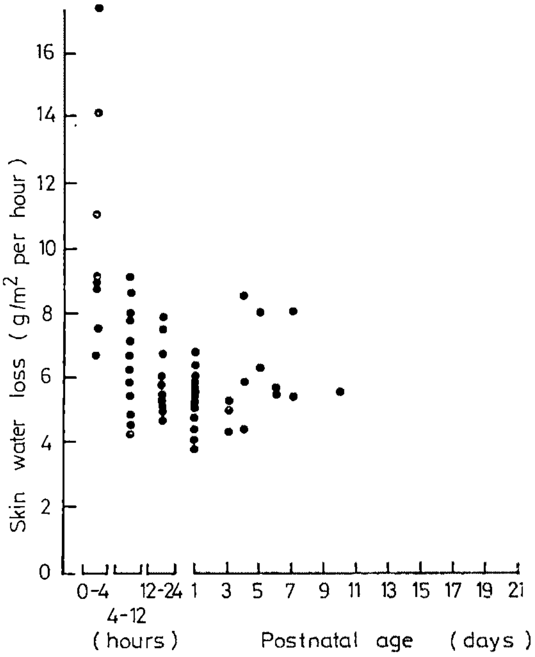

Fig. 1 *Skin water loss for babies of 38 to 41 weeks' gestation.*

Group 2 (Fig. 2)

Water losses in this group were also low and values were similar to those found in term babies. Measurements made in the first 4 hours averaged 11·0 g/m² per hour. After this time the average skin water loss was 6·0 ± 1·2 g/m² per hour. Babies who were light-for-dates did not differ from those who were appropriate for dates.

Group 3 (Fig. 3)

Skin water losses were considerably higher than in term babies and the fall in values after 4 hours of age was not seen. Average losses in the first week were 13·0 ± 3·5 g/m² per hour, but from the second week onwards were similar to those in term babies (7·8 ± 1·7 g/m² per hour). Babies who were light-for-dates did not differ from those who were appropriate for dates.

Group 4 (Fig. 4)

Skin water losses in these extremely preterm babies were very much higher than those seen in term ones, and again the fall in values after 4 hours of age was not seen. In the first 3 days losses averaged 32·4 ± 13·6 g/m² per hour. Losses were still high after the first week; 3 out of 5 babies studied serially at this time had losses 2 to 4 times greater than those of mature babies. Average losses from 4 to 7 days of age were 21·5 ± 8·0 g/m² per hour, from 8 to 14 days 15·7 ± 7·6 g/m² per hour, and from 15 days onwards 11·4 ± 4·8 g/m² per hour.

Water loss from individual sites (Table 2). As would be expected, the rates of evaporation at individual sites fell as both gestational age and postnatal age

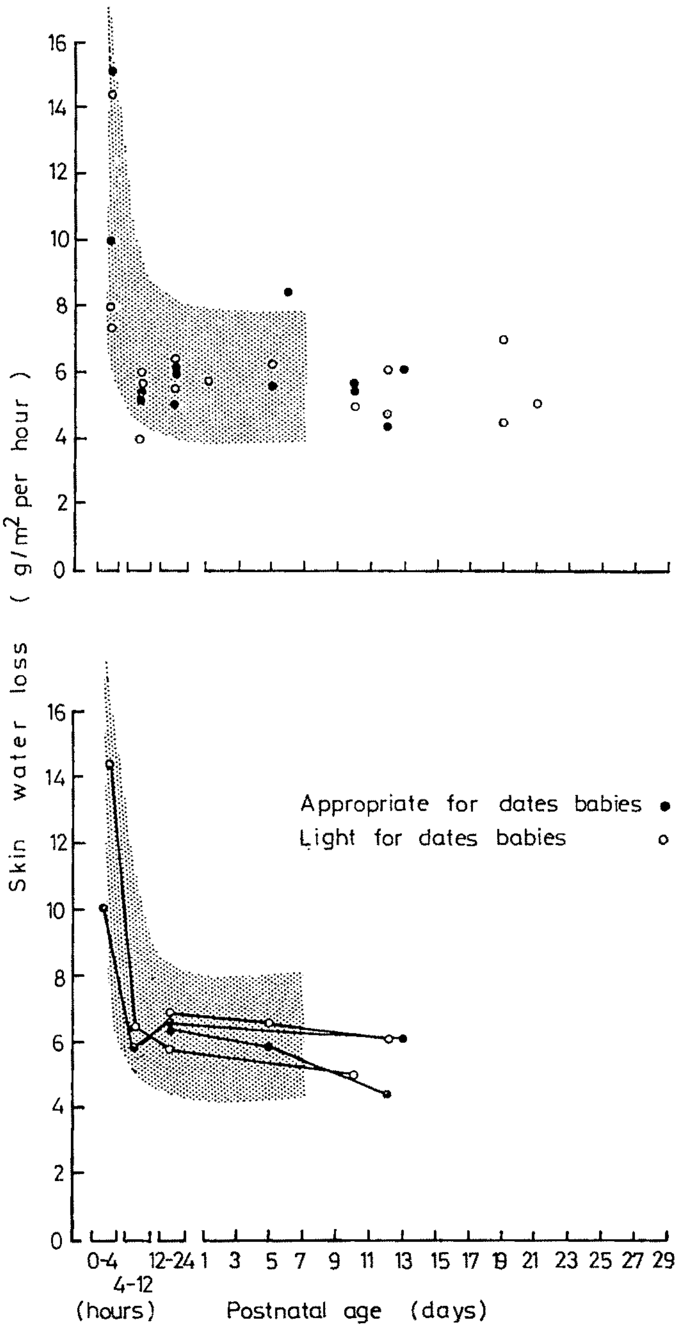

Fig. 2 *Skin water loss for babies of 34 to 37 weeks' gestation. Upper figure shows all the measurements made on babies in this group. Lower figure shows those measurements which were made serially on the same baby. Hatched area represents the range of skin water loss found in term babies (Fig. 1).*

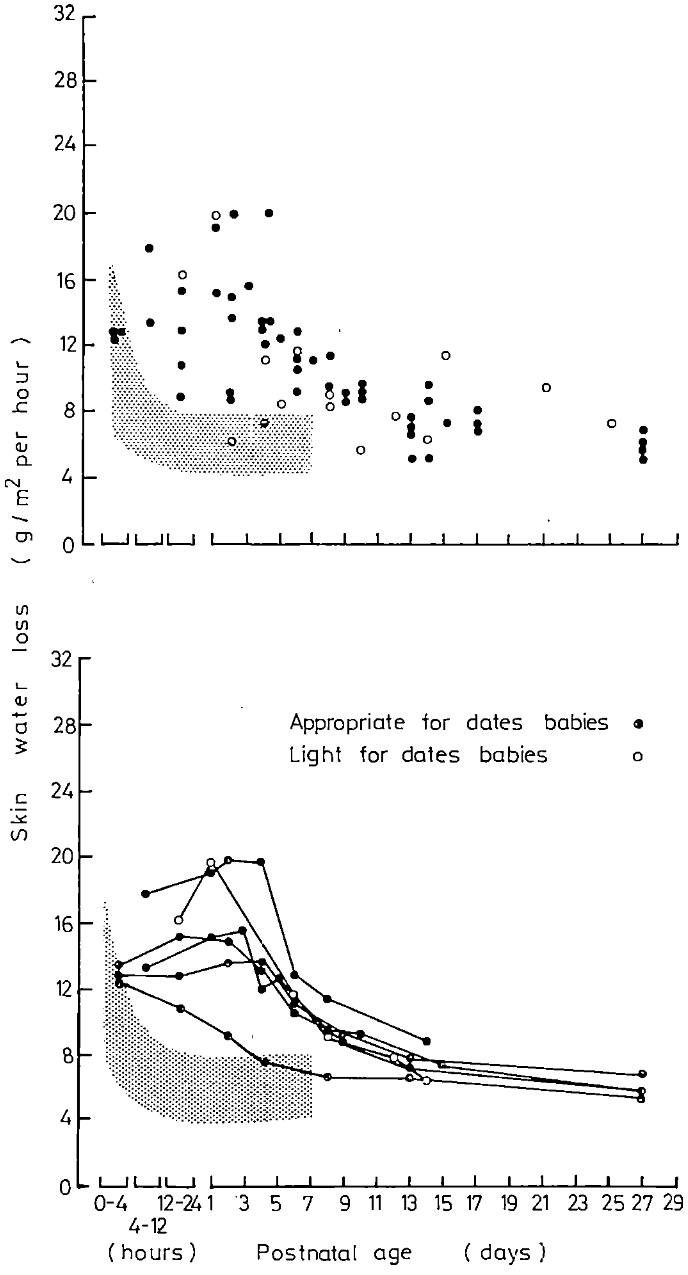

Fig. 3 *Skin water loss for babies of 30 to 33 weeks' gestation.*

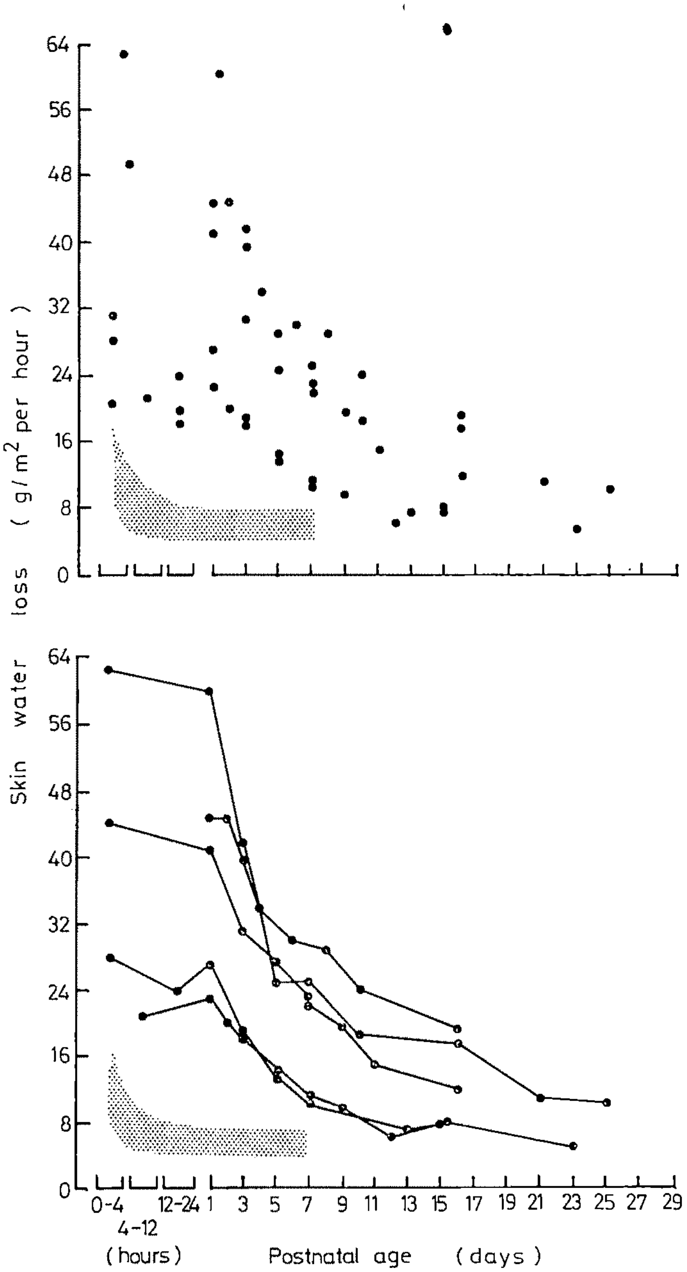

Fig. 4 *Skin water loss for babies <30 weeks' gestation.*

increased. A number of interesting findings emerged. In the most immature group of babies (group 4) the highest rate of water loss was found on the abdomen (Fig. 5). Lowest losses were found on the cheek, forehead, palm, and sole. As the babies grew older, all losses fell with the exception of those from the palm and the sole where water loss actually increased. A similar rise in water loss from these sites as the babies grew older was seen in the other preterm babies (groups 2 and 3). Term babies (group 1) had low rates of evaporation over most of the body but water losses from the palms and the soles were high.

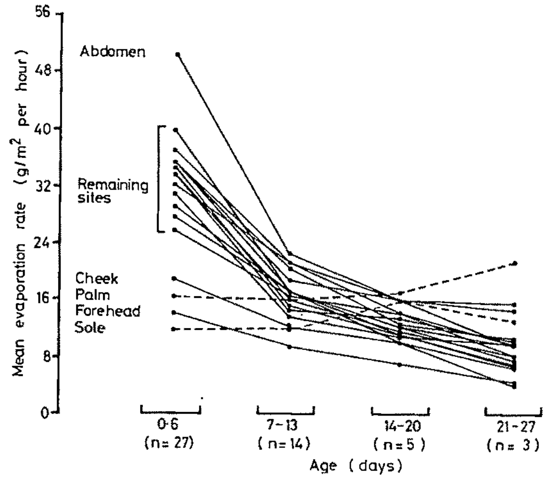

Fig. 5 *Mean rates of evaporation of water at 18 skin sites for babies <30 weeks' gestation.*

Discussion

It was perhaps surprising to find that the skin water loss of mature infants after the first 4 hours of life was lower than that of adults. Lamke *et al.* (1977) using Nilsson's method found average values in supposedly nonsweating adults to be about 12 g/m^2 per hour, compared with our values of 6 g/m^2 per hour in mature infants. In adults, over most areas water loss was about 8 g/m^2 per hour, but higher values of 20, 35, and 80 g/m^2 per hour were obtained from the forehead, soles, and palms respectively. Cunico *et al.* (1977) suggested that the higher values at these sites in a comfortable thermal environment were due to mild sweating. In both adults and babies, skin water loss and basal metabolic rate are directly related (Levine and Marples, 1930; Hey and Katz, 1969), so the higher water loss in adults might simply be due to the fact that they have higher metabolic rates per unit surface area than babies.

In both adults and term infants skin water loss was relatively higher from the palms of the hands and the soles of the feet (Hammarlund *et al.*, 1977; Lamke *et al.*, 1977) and we have confirmed this in term infants. Water loss from these sites is thought to be due mainly to sweating since the skin here is too thick to allow a high transepidermal water loss. This mental or emotional sweating is outside thermal control and is present over a wide range of ambient temperatures.

In the first 4 hours of life, the skin water loss in babies in groups 1 and 2 (34 to 41 weeks' gestation) was high and showed wide individual variation. All these babies were dried after birth with a warm towel and were not obviously wet when measured at least 2 hours later. The rates of water loss subsequently fell, suggesting that the surface of the skin was still drying out. It is well recognised that evaporative water loss plays a major part in the fall in body temperature which commonly occurs after birth.

Strikingly high losses were found in the immature babies. The more immature the baby, the higher was the skin water loss. Losses in babies who were light-for-dates were appropriate for their gestations. The highest skin water loss, about 60 g/m^2 per hour, was from a baby of 26 weeks' gestation weighing 660 g on the first 2 days of life. Several investigators have studied water loss in preterm infants, and various methods have been used. Hey and Katz (1969) measured the total evaporative water loss of naked term and preterm babies in a metabolic chamber and derived a skin loss from this by subtracting the measured respiratory loss. Although their study included a baby weighing 1·1 kg at 28 weeks' gestation, no difference in water loss between term and preterm infants was shown. However, Fanaroff *et al.* (1972), Wu and Hodgman (1974), and Marks *et al.* (1977) measured the insensible weight loss of preterm infants nursed naked in incubators using a sensitive balance and found relatively high weight losses, the average value of about 30 g/m^2 per hour in babies weighing <1·25 kg. Ambient temperature and humidity conditions were similar to ours. In magnitude these values are close to our own, which demonstrates that the higher weight losses of preterm babies are largely a consequence of water loss through the skin as opposed to the respiratory tract.

Although theoretically possible, it seems unlikely that the high losses in immature babies are a result of active sweating. Sweating in response to thermal stimuli has not been demonstrated in infants <210 days' postconceptual age (Foster *et al.*, 1969). Furthermore, in our study the most immature babies in the first week of life who showed the highest water losses, had lower skin and rectal temperatures than term babies (Table 1). Term babies had low water losses and were clearly not sweating. Water loss from the skin in immature babies is therefore predominantly transepidermal. Transepidermal water loss depends on two factors: the permeability of the epidermis to water, and the environmental conditions. The ambient temperature and water vapour pressure were similar in the term and preterm babies and cannot account for the high losses. The skin and rectal temperatures were often lower in the most immature babies which would tend to reduce transepidermal water loss. The high water losses can therefore only be explained by the properties of the epidermis itself. It has been demonstrated that the water-retaining properties of the epidermis are fairly evenly distributed throughout the stratum corneum. The dried, compact cells of the stratum corneum have a much greater resistance to water diffusion than the deeper aqueous epidermal cells (Scheuplein, 1972). The fibrous protein, keratin, which is the major constituent of the stratum corneum is thought to be the main barrier to water diffusion. The skin of the preterm baby looks and feels thin, these features being used in the assessment of gestational age. In the very immature baby <30 weeks' gestation it appears moist and the dermal blood vessels are easily visible. The stratum corneum is poorly developed and keratinisation, even of the palms and soles, does not occur until the 6th or 7th month of fetal life (Ernst, 1896). It seems likely therefore that the high water loss of preterm babies is the result of a lack of keratin. A preterm infant is a water-dwelling fetus forced to live in air; his skin must make premature adjustments to the new air interface. The more immature the infant, the greater the leak of water, and the longer it takes after birth for the leak to stop. However, even in the most immature babies, skin water loss falls to levels similar to those found in term babies after 2 or 3 weeks. This suggests that postnatal existence hastens functional maturation of the skin, possibly by stimulating the formation of keratin. It is consistent with the observation that the skin of extremely immature babies looks similar to that of a term infant by the time the baby is about one-month old

It is interesting that the highest rate of water loss in the most immature babies was found over the abdomen where the skin looks thinner and more transparent than at any other site. Similarly, the skin of the forehead, cheek, palms, and soles, which looks thicker than elsewhere, showed a lower permeability to water. Water loss from the palms and soles increased as the babies grew older, whereas losses at all other sites decreased. Furthermore, losses from palms and soles were higher in term babies. It seems likely that a proportion of the water evaporating from the skin of the palm and the sole in preterm babies in the first month is derived from sweat glands and represents the onset of emotional sweating.

Implications

From a knowledge of the surface area and the resting oxygen consumption of a baby, it is possible to estimate the total water loss from a baby's skin and the proportion of the baby's resting heat production that this evaporative heat loss represents (Table 3). Thus a term, 3·5 kg baby, one-day old, nursed naked in an incubator loses about 30 ml water from the skin each day (8 ml/kg per day). In terms of heat loss, this is equivalent to about 10% of the resting heat production. Clearly, water loss from the skin of a term baby is not of major

Table 3. *Estimated effects of skin water loss in two babies, one term (Case 1) and one extremely immature (Case 2), aged one day. Water and evaporative heat loss are low in Case 1. Case 2 however, has a high daily water loss and his evaporative heat loss from the skin exceeds his resting heat production. Even if his heat loss by radiation and convection is abolished, he must increase his heat production in order to maintain his body temperature*

	Case 1 (*3·5 kg, 40 weeks' gestation*)	*Case 2* (*0·9 kg, 28 weeks' gestation*)
Surface area (m^2) (Boyd, 1935)	0·2	0·1
Resting oxygen consumption (ml O_2/kg per min) (Hey, 1969)	6·5	5·5
Skin water loss (g/m^2 per hour)	6	32
Evaporative heat loss* from the skin (watts)	0·8	2·2
Resting heat production† (watts)	7·7	1·7
Evaporative heat loss from the skin as a % of heat production	$\frac{0\cdot 8}{7\cdot 7} \times 100 \simeq 10\%$	$\frac{2\cdot 2}{1\cdot 7} \times 100 \simeq 130\%$

*Latent heat of evaporation of water 580 cal/ml.
†1 ml O_2 = 4·83 cal.

importance once the skin has been dried after delivery. This however is not so for the very low birthweight, immature baby with a relatively high surface area in relation to body weight. A baby <30 weeks' gestation, weighing 0·9 kg, one-day old, nursed naked in an incubator loses about 75 ml water from the skin each day (about 85 ml/kg per day). In terms of evaporative heat loss, this exceeds his resting heat production. Hence, even if radiant and convective heat losses are eliminated, the baby can only maintain his body temperature by increasing his heat production. If the capacity to do this is limited, his body temperature will fall. This explains a clinical paradox. A very small immature baby nursed naked in an incubator frequently has a low rectal temperature. If radiant heat losses are eliminated by use of a Perspex radiant heat shield (Hey and Mount, 1966) and convective heat losses are abolished by raising the incubator air temperature to that of the baby's skin, the baby may still remain cold. This is because his high evaporative heat loss is greater than his maximum rate of heat production.

Controlled trials have shown that keeping small, 1–2 kg babies warm increases their chances of survival (Silverman *et al.*, 1958; Day *et al.*, 1964) and results in an increased rate of growth (Glass *et al.*, 1969). Immature babies, <1·0 kg birthweights have a very high mortality rate, while their rate of growth in the first few weeks of life is often extremely poor. If the high evaporative water losses from the skin of these immature babies were greatly reduced, their chances of survival and their growth rates might be considerably improved.

We thank the medical and nursing staff of the Department of Neonatal Medicine and Surgery, and the midwives of ward 3A Maternity Unit, Nottingham City Hospital for help, and the Special Trustees for Nottingham University Hospitals for financial support.

Role of viruses in febrile convulsions

HELEN M. LEWIS, JOHN V. PARRY, RUTH P. PARRY, HEATHER A. DAVIES,
P. J. SANDERSON, D. A. J. TYRRELL, AND H. B. VALMAN

Northwick Park Hospital and the Clinical Research Centre, Harrow

SUMMARY A disseminated viral illness was demonstrated by isolating a virus from the CSF, blood, or urine in 27% of 73 children who were admitted to hospital after a first febrile convulsion However, a viral aetiology could be implicated for 86% of the children after combining results of tissue culture, electron microscopy, mouse inoculation, complement fixation tests, and interferon assay. Parallel bacterial cultures showed a possible pathogen in 29% of children, but in only 4% was the pathogen isolated from the CSF, blood, or urine. No correlation was found between the nature of the pathogen (or evidence of its dissemination) and the severity of the convulsion, degree of fever, CSF protein, CSF white cells, or the WBC. The results suggest that a febrile convulsion could be a response to invasion of the blood stream or central nervous system by a micro-organism which is usually a virus. Invasion may be of such brief duration that successful isolation of the virus from the blood, CSF, or urine is not more commonly achieved.

Between ages 6 months and 5 years about 3% of all children suffer at least one convulsion in association with a febrile illness (Lennox-Buchtal, 1973; Nelson and Ellenberg, 1978). There is now greater understanding of the chemical and structural characteristics of the immature brain and of the role of pyrogens in the pathogenesis of fever, but no direct link has been discovered between the febrile and the convulsive state (Lennox, 1953; Ounsted, 1976a). It has been suggested that the convulsion depends on the nature of the infecting micro-organism in combination with fever, age, and genetic predisposition. Epidemiological studies from western Europe and the USA suggest that febrile convulsions are associated with upper respiratory tract infections and other illnesses which are assumed to be due to viruses (Miller *et al.*, 1960; Millichap, 1968; Lennox-Buchtal, 1973). Even if there is no convulsion, viral illnesses can produce abnormal neurological signs, and slowing of the EEG pattern, without detectable changes in the CSF (Wallace and Zealley, 1970). The febrile convulsion might be a cerebral manifestation of a generalised viral illness or even a direct effect of virus on the central nervous system.

In a study from Nigeria about half the cases of febrile convulsions were associated with malaria parasitaemia, but enteroviruses were isolated from the blood or CSF in 8 out of 105 children on whom virus isolation tests were performed (Familusi and Sinnette, 1971; Familusi *et al.*, 1972). Most other reports of the viruses identified in association with febrile convulsions have been limited to isolates from the throat or faeces or to serological tests (Wallace and Zealley, 1970; Stokes *et al.*, 1977). The aim of this study was to establish a viral diagnosis and to find viruses in the CSF, blood, or urine immediately after the convulsion.

Patients and methods

The study lasted from 1 November 1976 to 1 December 1977. The patients were between ages 6 months and 5 years and were admitted with a generalised or focal convulsion associated with a rectal temperature of at least 38°C recorded in hospital within 24 hours of the convulsion. None of the children had had a previous convulsion.

Every child was seen within 24 hours by the same clinician, who recorded, on a standard proforma, the medical and developmental history, the findings on examination, and a clinical diagnosis of the illness which accompanied the convulsion. Each patient was reviewed daily in hospital and again in outpatients department 3 weeks later.

Virological methods. Viral infections were detected by inoculation of tissue cultures, intracerebral inoculation of suckling mice for Coxsackie A viruses, electron microscopy for rotavirus, complement fixation tests, and interferon assay.

For viral cultures each prepared specimen was inoculated on to human embryonic lung fibroblasts (MRC5), Ohio HeLa cells, and secondary monkey kidney cells (Lewis *et al.*, 1979). CSF and heparinised blood were immediately inoculated into the tissue cultures and incubated in the treatment room where lumbar puncture and venepuncture were performed. Throat swabs in viral transport medium were kept at 4°C, and within 2 hours most were inoculated into tissue culture. Nasopharyngeal secretions were collected, as well as throat swabs, from 28 patients who entered the study after May 1977. Urine and stool specimens which could not be inoculated within 2 hours were stored at −70°C until inoculation. Faeces were suspended in nutrient broth, clarified by centrifugation, and the final supernatant was used for tissue culture, electron microscopy (Lewis *et al.*, 1979), and mouse inoculation.

Faecal specimens were screened for Coxsackie A viruses by intracerebral inoculation of litters of suckling mice on their first day of life (Melnick *et al.*, 1969). Throat swabs or nasopharyngeal secretions were used to screen those patients from whom no stools were obtained. When a screening specimen was positive all available specimens from other sites of that patient were examined.

Serological tests were performed on serum which was collected on admission, and again after an interval of 3 to 4 weeks. Complement fixation tests (CFTs) were performed against the following antigens: influenza A, influenza B, adenovirus, psittacosis, coxiella, measles, respiratory syncytial virus (RSV), *Mycoplasma pneumoniae*, mumps, herpes zoster, herpes simplex, Coxsackie B, cytomegalovirus, and parainfluenza 1, 2, and 3. Antibodies to rubella were sought by haemagglutination inhibition. All convalescent sera were screened; acute phase sera were only tested if a titre of 1/20 or higher was obtained. Results were regarded as positive if there was at least a 4-fold rise in titre between acute and convalescent sera.

The interferon activity of serum collected within 2 hours of admission was assayed by a plaque inhibition technique, on a semimicro scale, using continuous vervet monkey kidney cells in wells in plastic (Matthews and Lawrence, 1979). The serum was diluted 1:10 and left on the cell sheet for 24 hours at 37°C in a humid atmosphere containing 5% carbon dioxide. The monolayers were washed and vesicular stomatitis virus was added as the challenge virus.

A reduction of at least 50% in the mean plaque count was taken as indicating the presence of interferon. Dilutions of the MRC Research Standard B (69/19) for human interferon were included with each test, and 1 unit of this was found to give between 50 and 70% reduction.

Bacteriological methods. CSF was sent to the microbiology department for immediate microscopy and culture. Blood was incubated at 37°C in glucose broth and thioglycollate, subcultures were made aerobically and anaerobically. Throat swabs were taken on serum-coated wool buds. In the first part of the study they were transported in Stewart's medium and plated within 4 hours. From July 1977 all throat swabs were taken by the same clinician, who plated them immediately on to blood and chocolate agar. Colonies were identified by standard techniques and all β-haemolytic streptococci were grouped serologically. Urine specimens were inoculated on to CLED medium within 4 hours of collection. Colonies were enumerated and identified by standard techniques. A significant growth was taken as $>10^8$ organisms/litre. Fresh stool specimens were plated on to deoxycholate agar and MacConkey agar and inoculated into selenite broth. Enteropathogenic *Escherichia coli* were identified by using antisera to 15 recognised enteropathogenic types (PHL Colindale). From April 1977 a selective medium was used to isolate campylobacter species (Skirrow, 1977).

Additional tests were WBC of the peripheral blood, plasma glucose level, and CSF protein and glucose concentrations.

Results

37 boys and 36 girls were studied. The mean age was 18·9 months and only 3 (4%) children were over 3 years. Two children were excluded because virological investigation had been omitted; one had meningitis, with *Haemophilus influenzae* cultured from the blood and CSF; the other child had clinical measles. All other patients admitted during the study period were retained, although a complete set of microbiological specimens was not obtained from every patient; there was sometimes insufficient serum for interferon assay and a few patients did not return for convalescent serology.

Virology results. A virus was identified from at least one site in 46 (63%) out of 73 patients. The viruses are named in Table 1; from 9 patients, viruses of more than one type were identified.

There was a significant rise in antibody titre in 14 (20%) out of 69 patients. All had a 4-fold response

except one, with doubling of an initially high titre; from 11 of these patients a virus of the same type was isolated by tissue culture. A rise in antibody titre to RSV was demonstrated in 2 cases, but the virus was not isolated; in addition one of these patients was shown to be infected with an adenovirus by CFT and culture, and the other also had a positive measles CFT.

Interferon was detected in the serum of 31 (47%) out of 66 patients. From 16 of these a virus was isolated; there was no other evidence of a viral illness for the remaining 15 patients.

63 (86%) out of 73 patients had some evidence of a viral illness when all the methods were considered together—that is tissue culture, electron microscopy, mouse inoculation, serology, and interferon assay.

Evidence of a systemic viral illness was demonstrated in 20 (27%) cases by isolating a virus from the CSF, blood, or urine. A virus was isolated from the CSF of 4 patients, from the blood of 12, and from the urine of 13 patients (Table 2).

Bacteriology results. Pathogenic bacteria were isolated from 21 (29%) patients, Table 3. There was no difference in the isolation rate when throat swabs were plated immediately rather than transported in Stewart's medium.

A systemic bacterial illness was demonstrated in 3 (4%) cases. From one patient *H. influenzae* was isolated from the blood and CSF. Two patients had a significant *E. coli* bacteriuria, which was confirmed on subsequent specimens. From 14 of the patients with a bacterial isolation a virus was also recovered.

Interferon was detected in 9 cases with a bacterial isolation but a virus was also recovered from 5 of these.

Other investigations. The patient with *H. influenzae* meningitis had a high CSF WBC and a high CSF protein level; of the rest only one patient had more than 4/mm^3 white cells in the CSF, and one had a CSF protein $>0{\cdot}4$ g/l (40 mg/100 ml). There was no relationship between the CSF findings and the nature of the pathogen, or evidence of viral dissemination.

The WBC did not distinguish those with bacterial isolations from those with viral isolations. However, a group of patients from whom adenoviruses were identified had significantly higher white cell counts than any others, i.e. 80% of patients with adenovirus isolations had >15 000/ml (mainly polymorphs) compared with 36% of patients without adenovirus ($\chi^2 = 9{\cdot}8$, $P<0{\cdot}01$).

Clinical data

From the histories given by the parents perinatal asphyxia may have occurred in 6 cases. Later in the first year of life one infant had an asphyxial episode but the others had an unremarkable medical history. The probability of normal developmental achievement before the convulsion was indicated by asking the mothers the ages at which their children had achieved four major milestones (Neligan and Prudham, 1969). 66 (90%) children had reached all four milestones by the ages expected for 90% of children of their own sex, and no child failed more than one milestone. Thus the developmental achievements of the group were no different from those of the general population. We therefore cannot verify that perinatal problems and abnormal development are commonly found in children suffering febrile convulsions (Millichap, 1968; Wallace, 1972, 1975). A parent or sibling of 8 (11%) of our children was known to have suffered from febrile convulsions and a further 6 (8%) had each suffered at least one convulsion which was not associated with fever.

The mean length of illness before the convulsion was 13·4 hours (range 0 to 96). The symptoms noted by the parents were nonspecific: irritability, anorexia, and fever were commonly recorded but cough, vomiting, or diarrhoea sometimes indicated the likely site of infection.

+ Virus isolated, – no virus isolated, 0 no specimen taken.
URTI = upper respiratory tract infection, PUO = pyrexia of unknown origin, NPS = nasopharyngeal secretions.

The mean rectal temperature recorded immediately after admission was 39·5°C and ranged from 37·5 to 42°C. 11 (15%) children had received at least one dose of an antibiotic before collection of specimens for microbiology.

The clinical diagnoses of the precipitating illnesses were classified according to the guidelines suggested by Court (1973). An upper respiratory tract infection (URTI) was further described as coryza, tonsillitis, pharyngitis, or otitis media if the predominant symptoms or signs were localised to the nose, tonsils, pharynx, or tympanic membranes respectively. In Tables 1, 2, and 3 the diagnoses are tabulated against the pathogens which were subsequently identified. A morbilliform or maculopapular rash was reported during the illness of 14 patients, and pathogens identified from these cases are listed in Table 4. No pathogens were found in 18 patients whose diagnoses were tonsillitis (1), pharyngitis (2), otitis media (3), coryza (1), URTI (7), gastroenteritis (2), gastroenteritis with URTI (1), and pyrexia of unknown origin (1).

Upper respiratory illnesses were found in 59 (81%) of all patients and gastrointestinal illnesses in 9 (12%). These figures are close to those recorded in other surveys (Millichap, 1968).

49 (67%) patients had had fits each one lasting under 15 minutes, which was not followed by further fits in the same illness, and was not accompanied by localising signs. These were classified as 'simple fits'. One or more 'complex' features occurred in the remaining 24 (33%) patients. Eight patients had fits which each lasted longer than 15 minutes (but only 2 convulsed for longer than 30 minutes). 10 patients had more than one convulsion in the same illness, and 5 patients had localising features or a

virus in the CSF but one of these (Case 59) had *H. influenzae* meningitis (Table 2).

No relationship was found between 'complex' features and the WBC of the CSF or blood or the temperatures recorded after admission.

Microbiological findings in gastroenteritis

A concurrent but separate study of gastroenteritis comprised 150 children whose ages were similar to those with febrile convulsions (Lewis *et al.*, 1979). Both projects were undertaken by the same people and microbiological methods were identical. Viral and bacterial cultures were taken from stools and throat swabs, and stools were examined for rotavirus by electron microscopy. CSF, blood, and urine were not collected, nor were mouse inoculation tests performed.

The two groups of patients are compared in Table 5. Significantly more patients with febrile convulsions carried viruses in their throats. In gastroenteritis, rotavirus was by far the most common pathogen and bacterial pathogens were more often identified in the stool.

Discussion

The results indicate that common viruses can invade the blood stream and CSF and, presumably, the central nervous system. We suggest that systemic invasion occurred in all cases and was important in producing both fever and convulsion. We failed to isolate a virus from all specimens of blood and CSF because we took very small (1 ml) quantities, and we suspect that the virus was rapidly eliminated from these sites as the child recovered from the convulsion.

The study has shown a viral aetiology in a higher proportion of patients than others have reported (Wallace and Zealley, 1970; Familusi *et al.*, 1972; Stokes *et al.*, 1977), probably because several methods of viral diagnosis were used. Tissue culture from fresh specimens gave the highest number of positive results, and additional viruses were detected by electron microscopical examination and inoculation of suckling mice. Complement fixation tests were rarely positive, but we did not seek an immune response further by titrating neutralising antibody against the specific viruses cultured. Interferon assay was an indication of viral illness rather than definitive diagnosis. We detected interferon in the serum of 16 (36%) out of 45 patients from whom a virus was identified by tissue culture or serology, but we also found interferon in 15 patients from whom no virus was isolated. A previous study from this unit detected interferon in the acute phase serum of 17 (38%) out of 45 children and adults with a proved virus infection, but from none of 25 with bacterial, mycoplasma, or rickettsial infections, or from 61 healthy persons (Matthews and Lawrence, 1979). We suggest that a virus was present but not demonstrated in our 15 patients with interferon but no other evidence of viral infection. This is not an unreasonable assumption as we did not perform tests for a number of viruses, including EB virus and hepatitis viruses.

We cannot prove that the viruses we identified were responsible for the illnesses which precipitated the convulsions, but we have good supportive evidence.

Firstly, a virus of the same type was often isolated from multiple sites in the same patient, and there was no cross contamination. The complement fixation tests often (but not always) corroborated the findings.

Secondly, the clinical features associated with the viruses agree well with those described in reports (Tables 1, 2, and 3). Thus, the adenoviruses and the parainfluenza viruses were particularly associated with tonsillitis and otitis media (Medical Research Council, 1965; Gardner, 1968; Clarke, 1973; Pereira, 1973). Diarrhoea was associated with rotavirus and with adenoviruses (Du Pont *et al.*, 1977; Walker-Smith, 1978). Rashes were observed with measles virus and Coxsackie A viruses (Table 4). Coxsackie B1 was identified in the stool and throat swab of a patient who had gastroenteritis followed by orchitis, and an enterovirus was found in 3 out of 4 children for whom pyrexia of unknown origin was the only diagnosis (Dalldorf and Melnick, 1965; Melnick, 1965; McLean, 1966). Four patients were immunised in the 2 weeks before their convulsions, but in 2 (DTP and polio vaccines) viruses were isolated which were possibly of more significance than the vaccine in precipitating the convulsion; in the third case cholera vaccine was given 1½ hours before the temperature suddenly rose with a convulsion and an unusually severe local inflammatory response. In the fourth case measles virus was isolated from the blood of a child who had measles vaccine 10 days before the convulsion. We have seen no other documented case of measles viraemia attributed to the febrile reaction to immunisation (Landrigan and Witte, 1973).

The different pattern of viruses identified in children with gastroenteritis adds further support to the validity of our findings (Table 5). Rotavirus has always been associated with diarrhoea, but adenoviruses and enteroviruses could be responsible for either respiratory or gastrointestinal illness, depending on their site of maximal multiplication (Dalldorf and Melnick, 1965; Ginsberg and Dingle, 1965; Melnick, 1965; Pereira, 1973; Steinhoff, 1978). Of doubtful significance were bacterial pathogens in throat swabs, which were isolated with similar frequency in gastroenteritis and febrile convulsions, and have been commonly found in the throats of healthy young children (Masters *et al.*, 1958; Gardner, 1968). Although many children with febrile convulsions had clinical tonsillitis, a haemolytic streptococcus group A was isolated from only one throat.

We have implicated a systemic viral illness in the majority of febrile convulsions, but a generalised bacterial illness was possible in 3 (4%) cases where a bacterial pathogen was isolated from the CSF, blood, or urine (Table 3). The first child (Case 59) had clinical meningitis attributed to *H. influenzae*; we cannot explain the significance of finding two types of adenovirus in the CSF, blood, throat, and urine of this patient (Table 2). The second child had *E. coli* bacteriuria, but *E. coli* in a subsequent blood culture confirmed a diagnosis of bacterial endocarditis. The third patient (Table 2, Case 27) had significant but asymptomatic bacteriuria with clinical otitis media; an adenovirus was isolated from the CSF and urine, and there was a rising CFT titre to adenovirus.

We investigated only those with convulsions but transient viraemia or bacteraemia may occur in other children during acute febrile illnesses. We suggest that a convulsion occurs when a child with a predisposition to febrile convulsions is exposed to a systemic virus or bacterium at an age when the immature brain is susceptible (Coyle, 1976; Ounsted, 1976b). We had evidence of no predisposing factors except family history. After one year the occurrence of subsequent febrile convulsions in our cohort bears no relationship to the nature or site of the pathogen in the initial episode.

It has recently been shown (Stephenson, 1978) that not all febrile convulsions are classical epileptic paroxysms but some may be related to vagal reflexes. We may therefore have studied the microbiology of a heterogeneous group of central nervous system phenomena described as 'febrile convulsions'. We hope that more thorough virological investigations will be undertaken in conjunction with electrophysiology, immunology, and epidemiology to show how viruses can affect the central nervous system in different ways, ranging from a brief convulsion to a florid encephalitis or to a slow virus illness such as subacute sclerosing panencephalitis.

We thank the technicians in the Department of Microbiology, Mrs A. Mott and Dr E. C. Coles for statistical advice, Mrs R. C. White for typing the manuscript, Dr M. Liberman for allowing us to study patients, and the nursing staff and house physicians of Carroll Ward for assistance.

Family resemblances of height, weight, and body fatness

L. J. HAWK AND C. G. D. BROOK

Department of Paediatrics, Middlesex Hospital, London

SUMMARY In a study of 256 families, among whom were twins, midparent-adult *son* correlations for height, weight, and combined skinfold measurements were 0·67, 0·47, and 0·23 respectively. The corresponding midparent-adult *daughter* correlations were 0·63, 0·42, and 0·24. Midparent-growing offspring correlations were highest for height, less for weight, and insignificant for combined skinfold measurements. These data and the resemblances found between twins and siblings led us to conclude that there is a significant genetic contribution to the variation of height and weight, but that body fatness appears largely to be determined by environmental factors.

Twin studies have suggested body fatness in childhood to be largely genetically determined (Brook *et al.*, 1975; Börjeson, 1976). Parent-growing offspring correlations for skinfold measurements, however, have been found to be low (Garn and Clark, 1976; Mueller and Titcomb, 1977) and to be of similar value to parent-adopted child skinfold correlations (Garn *et al.*, 1976). As body fatness may be influenced by environmental factors—for example exercise and diet (Parizkova, 1963; Sims *et al.*, 1968), resemblances between relatives may, more than anything else, reflect their shared common environments.

In this study, correlation coefficients of body fatness between various family members have been calculated and compared with correlations found for weight and height, the last being generally considered to be largely genetically determined (Pearson and Lee, 1903).

Materials and methods

Between 1961 and 1962, the heights and weights of parents and offspring and the skinfold measurements of offspring aged 2 to 15 were recorded for 330 families (Huntley, 1966). An attempt was made to trace these families, among whom were twins. Heights, weights, and skinfold measurements were recorded on parents and offspring. Heights were measured on a Holtain portable stadiometer, weights on beam scales (the subjects wearing underclothes only), and skinfolds with Holtain calipers at the triceps, biceps, subscapular, and suprailiac sites (Weiner and Lourie, 1969).

The distribution of the skinfold measurements was logarithmic. Log transformation of the data normalised the distribution (Edwards *et al.*, 1955). Log-transformed data were used in the analysis.

The sum of the 4 skinfold measurements was used to indicate body fatness (Parizkova, 1961; Durnin and Womersley, 1974). As skinfold measurements change with age, and as the subjects were measured at widely different ages, standard deviation (SD) scores for the combined measurements of each individual were calculated. The means and SDs against which each individual was compared were the means and SDs for that individual's year group, calculated from the study population.

Weights of adult offspring were compared with the earlier weights of their parents recorded between 1961 and 1962. Heights were compared directly between adult offspring and their parents. Skinfold thickness SD scores were used to compare skinfold thicknesses between offspring and parents.

Results

296 (89%) of the families were traced and 256 (78%) remeasured. The mean heights and weights of the parents and of the offspring, now aged at least 20 years, are shown in Table 1.

Parent-adult offspring correlations of height, weight, and skinfold thickness are shown in Table 2. The relationships between the anthropometric

Paediatric Department, Middlesex Hospital, London
L. J. HAWK, research fellow
C. G. D. BROOK, consultant paediatrician

measurements in the parents and in their growing children varied from age to age. The yearly figures are available on request from the authors: values for parent-growing offspring correlations were highest for height, less for weight, and insignificant for skinfold thickness.

Table 1 *Heights and weights (mean ± SD) of adult offspring and their parents*

	Height (cm)	*Weight (kg)*	*Mean age at time of measurement*
Fathers (n = 186)	172·4 ± 0·52	73·7 ± 0·79	42·2
Mothers (n = 211)	162·9 ± 0·40	62·3 ± 0·53	39·7
Sons (n = 345)	177·5 ± 0·38	69·2 ± 0·57	25·2
Daughters (n = 341)	164·1 ± 0·33	57·6 ± 0·48	24·9

In childhood				
Heights	0·95	0·99	0·95	0·95
Weights	0·99	0·99	0·88	0·79
Combined skinfolds	0·81	0·81	0·48	0·51

Table 4 *Resemblances between siblings for combined skinfold measurements*

	Childhood	*Adult*
One in each pair a twin		
Brother-brother	0·34 (68)	0·36 (60)
Sister-sister	0·19 (38)	−0·03 (48)
Neither in pair a twin		
Brother-brother	0·20 (15)	0·30 (25)
Sister-sister	0·34 (13)	0·05 (20)

Analyses of the twin data in childhood and in adult life are shown in Table 3. Resemblances between siblings for combined skinfold measurements in childhood and in adult life are shown in Table 4.

Discussion

The secular trend in height is clearly shown in Table 1. The individual parent-offspring correlations (Table 2), which come close to those anticipated by Fisher (1918) for fully genetically determined characteristics, indicate that adult height is largely genetically determined. For such a characteristic, the regression coefficients of offspring on midparent (1·0) and midparent on offspring (0·5) will give a correlation coefficient of 0·71. Our data show values which approach this and agree with previously published figures (Brook *et al.*, 1977).

The skinfold measurements, by contrast, showed no such pattern. No resemblances were found between parents and their offspring, either as children or as adults. Sisters did not resemble one another and brothers only slightly. There is little suggestion of any genetic contribution to body fatness levels from these data.

On the other hand, correlations of skinfold thicknesses between twins in childhood taken on their own suggest a very considerable genetic contribution to the variation in skinfold measurements. The adult values were different: while monozygotic twins continued to resemble each another closely, the male dizygotic twins resembled one another more than had been the case in childhood and the female dizygotic twins showed no resemblance at all.

The parents' skinfold measurements were not taken in the first study and at the time of the second one about three-quarters of the offspring no longer lived at home. All the parent-growing offspring skinfold correlations and most of the parent-adult offspring skinfold correlations therefore reflect the fact that parents and offspring were not sharing common family environments. The lack of resemblances found in this study compared with the positive correlations found in others between parents and offspring when the offspring were still living at home (Garn and Clark, 1976; Mueller and Titcomb, 1977), suggests common family environment to be the important factor in the determination of body fatness, which the twin data do not negate.

The use of differences between monozygotic and dizygotic twins to assess the relative importance of genetic and environmental contributions to the determination of the variation of a characteristic depends upon the assumption that twins are treated more or less similarly whether they are identical or nonidentical. Smith (1965) noted many more similarities in environmental factors between identical twins in childhood compared with nonidentical twins. Twins who look alike were treated alike. Consequently, for a characteristic largely environmentally determined, it could be anticipated that identical twins would resemble each other more in childhood than nonidentical twins.

In collecting data from the adult twins, an attempt was made to assess activity levels. There were too many variables for satisfactory statistical analysis, but an extraordinary similarity in lifestyles and habits was noted between the identical twins. The male nonidentical twins also shared much in common and took advantage of having a brother of the same age with whom to share sporting interests. The nonidentical female twins, on the other hand, showed little in common. The resemblances in body fatness between the adult twins reflected these differences and the lack of resemblance with their singleton brothers and sisters was conspicuous.

The results for body weight lay between those for height and skinfold measurements, as would be anticipated, as weight includes both. The correlations more closely resembled the findings for height, probably because there were few obese subjects in the study group. All our analyses confirmed the widely held view that weight is conspicuously unreliable as a measure of body fatness.

Genetic factors play a large part in the determination of adult height; environmental factors largely determine adult body fatness levels. Figures derived from twin data alone should be regarded with a considerable degree of suspicion.

Ethnic differences in the Goodenough–Harris draw-a-man and draw-a-woman tests

A. E. DUGDALE AND S. T. CHEN

Department of Child Health, University of Queensland, and the Department of Paediatrics, University of Malaya

SUMMARY The draw-a-man (DAM) and draw-a-woman (DAW) tests were given to 307 schoolchildren in Petaling Jaya, Malaysia. The children were ethnically Malay, Chinese, or Indian (Tamil), and all came from lower socioeconomic groups. The standard scores of the Chinese children averaged 118 in the DAM and 112 in the DAW tests. These scores were significantly better than the American standards. Malay children scored significantly lower than Chinese, and Tamil children scored lower again. The nutritional status of the children had no influence on the scores. Chinese and Tamil children scored better in the DAM than the DAW, while in Malay boys the reverse was true. Malay children tended to emphasise clothing in the DAM, but Chinese and Tamil children scored better on items relating to facial features and body proportions. The Goodenough–Harris draw-a-person tests are obviously not culture-free, but the causes of ethnic differences have not been elucidated.

A child's performance in an intelligence test depends on his cultural background, his genetic intellectual potential, and his motivation. Most tests have been designed to match the cultural background of middle-class American or Western European children and cannot safely be used with other groups. However, one test which has the potential of being truly cross-cultural is the Goodenough–Harris draw-a-person test. The human form is universally available as a model, and figure drawing is common among children of all ethnic groups. We used this test on groups of schoolchildren from similar socioeconomic levels but very different cultural backgrounds to try to find whether significant variability existed.

Methods

Malaysia is particularly suited for cross-cultural studies. In the cities, there are peoples of Malay, Chinese, and Indian backgrounds living side by side, but still retaining their own vernacular and customs. Within each ethnic group, the families range from affluent to very poor, and nutritional levels also vary widely. Children from poorer families usually attend vernacular schools intermittently and leave early.

There were data on 307 children, although not all information was available for some. The data used in this study were (1) Age; this was obtained from birth certificates and ranged from 6½ to 10½ years. (2) Sex of the child. (3) Ethnic group; there was no intermarriage or ethnic mixing among the groups studied. (4) Type of school. Malay and Indian children were taught in their vernacular language, Malay and Tamil respectively. Chinese children attending Chinese language schools were taught in Mandarin, although their vernacular languages were generally Cantonese or Hokkien. (5) Number of children currently at home. (6) Family income; this was obtained by questioning the parents. (7) Number of years' schooling of each parent. (8) Height and weight of the child. This was converted to a percentage of the Stuart and Stevenson standard for a child of that age and sex (Nelson, 1964). (9) The Goodenough–Harris draw-a-man (DAM) and draw-a-woman (DAW) tests; these were done in the school classrooms, and raw scores were converted to standard scores using the tables given by Harris (1963).

The children whose drawings have been used in this study were all attending government primary

schools in Petaling Jaya, a satellite city of Kuala Lumpur, the capital of Malaysia. These schools are free and, because at the time of the study most teaching was done in vernacular language, each school had predominantly pupils from one ethnic group (for further details see Dugdale and Chen, 1977).

Medical students doing their paediatric posting in the University of Malaya ran a School Health Service under the supervision of S.T.C. Children were seen class by class by the medical students. The DAM and DAW tests were done in the classroom by the whole class.

Because the child's name appeared on his drawings, it was not possible to score the test 'blind'. However, the scoring method was objective and standardised, so knowledge of the race of the child should have had little or no effect on the scoring.

Results

Overall scores in the DAM test. The mean values of the standard scores in the DAM and DAW tests are shown in Table 1. The scores are standardised on American children to have a mean of 100 and a SD of 15 points. The distribution of the DAM scores is shown in Fig. 1.

When compared with expected American standard scores, the Chinese children, boys and girls, scored higher (Kolmogorov-Smirnov 2-sample test, $P < 0{\cdot}01$) than American standards, but Chinese boys and girls did not differ significantly one from the other. On the other hand, Tamil children scored lower than American standards ($P < 0{\cdot}05$) and again boys did not differ from girls. Among Malay children, neither boys nor girls differed from one another or from American standards, although in Malay girls the higher mean score approached the level of significance ($0{\cdot}1 > P > 0{\cdot}05$). Within the three ethnic groups Chinese children scored higher than Malays ($0{\cdot}05 > P > 0{\cdot}025$), who in turn scored higher than the Tamil children ($0{\cdot}05 > P > 0{\cdot}025$). A few Tamil children drew men in long robes (see Fig. 3c) which would detract from the score. However, even allowing for this, Tamil children scored badly.

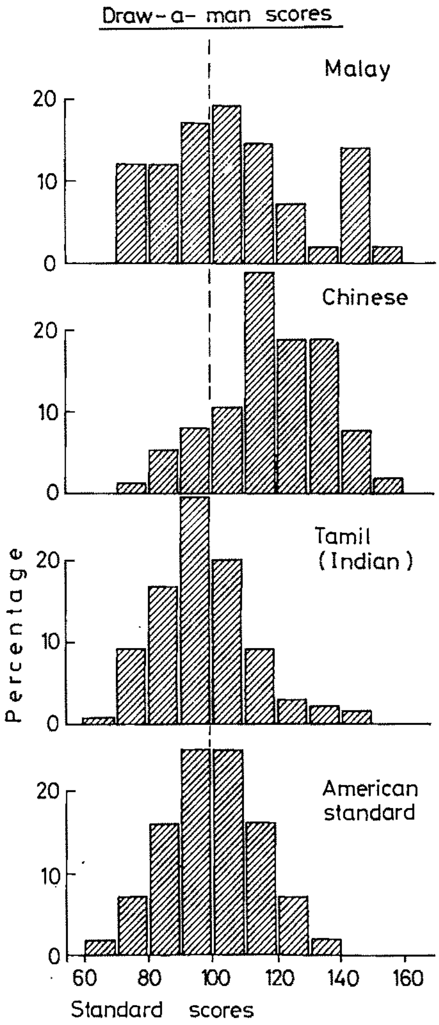

Fig. 1 *Distributions of scores in the DAM test in children of different ethnic groups. American standard score is shown at the bottom.*

Overall scores in DAW test. The mean scores are shown in Table 1 and the distributions are shown in Fig. 2.

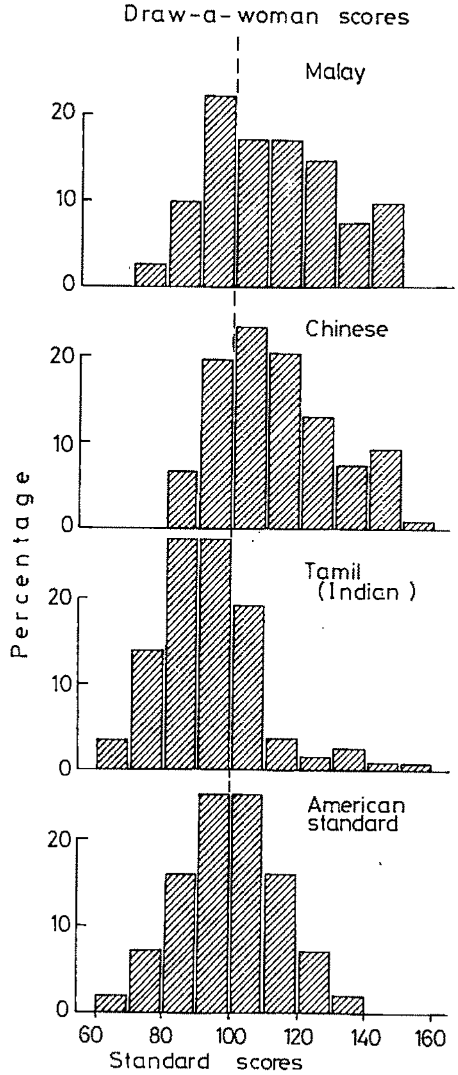

Fig. 2 *Distributions of scores in the DAW test. American standard score is shown at the bottom.*

Within each ethnic group, there were no significant differences between boys and girls. As with the DAM test, Chinese children scored higher than the American standards (P<0·01) and Tamil children lower (P<0·01) while Malay children tended to be better, but this did not quite reach the P = 0·05 level of significance. There were no significant differences between Malay and Chinese children, but these two groups had much higher scores than Tamil children (P<0·001).

Effects of nutrition and other environmental factors on scores. Because of the high correlation (r = 0·80) between DAM and DAW scores the mean value of the DAM and DAW was used as the dependent variable in the analysis. Multiple regression analysis was performed using the percentage present weight-for-age of the child as an indicator of nutritional status, family size, family income, and educational achievement of the parents as independent variables. These data were available on 263 children. Only 18% of the variance in the DAM and DAW scores was accounted for by these factors, and family income was the only significant single factor. Further testing with the extended median test showed that sex of the child had no effect on the scores. Although all children came from poor families, the Chinese families had slightly higher monthly incomes than the Malays, who again had slightly higher incomes than Indians. The DAM and DAW scores were recalculated to make allowance for these variations in income, but the statistically significant differences in the scores were unchanged. It is interesting that the current nutritional status of the child did not affect the score.

Relationship between DAM and DAW scores. An interesting pattern was found in the levels of the DAM and DAW scores among children of different ethnic groups (Table 2).

Among the Chinese children, both boys and girls scored significantly higher in the DAM than in the DAW test. A similar result was found in Tamil children. However, Malay boys scored better in the DAW than the DAM (P ≃ 0·02) and Malay girls showed no significant difference between the two tests.

Differences in patterns of drawing. Apart from diversity in overall scores, children from various

Table 2 *Pattern of scoring in the DAM and DAW. Numbers in each group were treated using χ^2 against the hypothesis that the two patterns of scoring should be equal. Children with tied scores are omitted.*

Tamil			
Boys	46	16	<0·01
Girls	53	24	<0·001

ethnic groups tended to emphasise different features of their drawings. We examined this by analysing the 73 individual items of the DAM score. For children in each ethnic group the items have been ranked in order of decreasing frequency of scoring. That is, an item which was scored positive in every child is ranked first, and items in which no child scored are ranked last. The rankings obtained for the three groups of children were compared, and items showing wide variation in ranking noted. In this way different patterns of drawing could be detected without interference of the variation in total scores. There were 7 items where the difference in rankings among the three groups was $\geqslant 20$ (items 15, 18, 19, 22, 23, 38, and 52) and a further 9 where the rank differences were $\geqslant 15$ (items 13, 29, 48, 50, 55, 56, 58, 59, and 62). When these differences were tabulated a distinct pattern emerged (Table 3).

Table 3 *Pattern of scoring of individual items in the DAM*

Group of children	*Less commonly found features*	*More commonly found features*
Malay	23 Proportion and position of ears	55 Clothing I
	62 All body parts in proportion	56 Clothing II
	18 Hair I	58 Clothing IV
	19 Hair II	59 Clothing V
	22 Ears shown	52 Tapering of arms
Chinese		15 Projection of chin
		29 Wrist and ankle shown
		50 Proportions of face
Indian	55 Clothing I	38 Knee shown
		22 Ears shown
		13 Nose and lips in two dimensions
		48 Proportions of head

The most striking differences were among the Malay children who tended to score well on clothing and poorly on body proportions and facial features. Indian (Tamil) and Chinese children tended to emphasise facial features and there may be a tendency for Tamil children to score poorly on items related to clothing. The various items in the scoring system are not independent, so statistical tests could not be used to find the significance of these patterns. Examples of drawings showing these differences are shown in Fig. 3a, b, c.

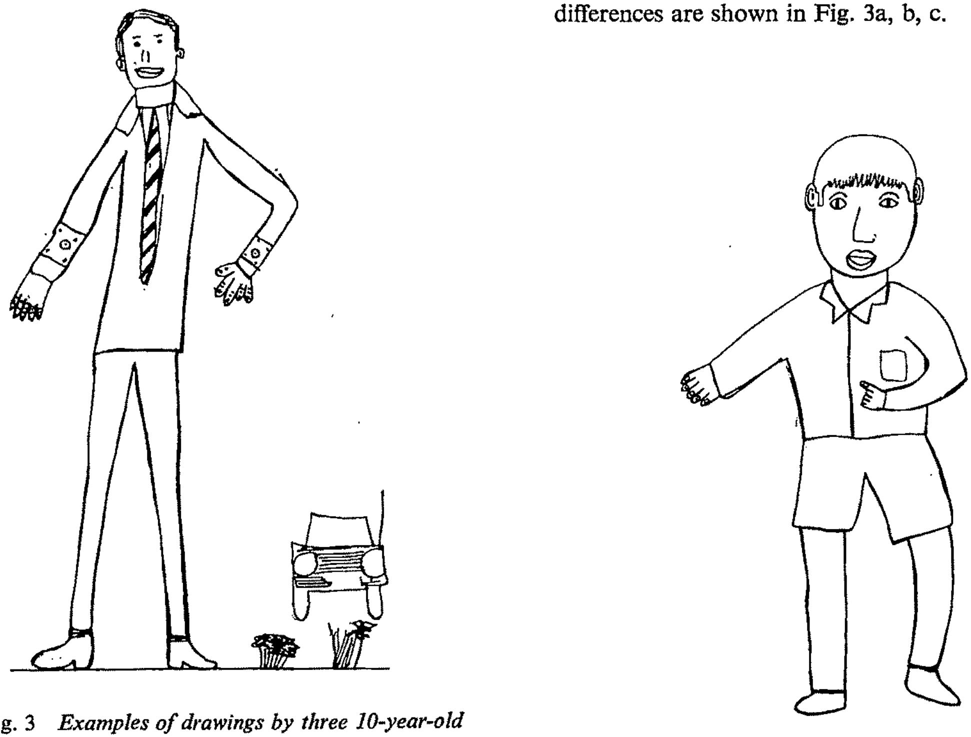

Fig. 3 *Examples of drawings by three 10-year-old children of different ethnic groups.*

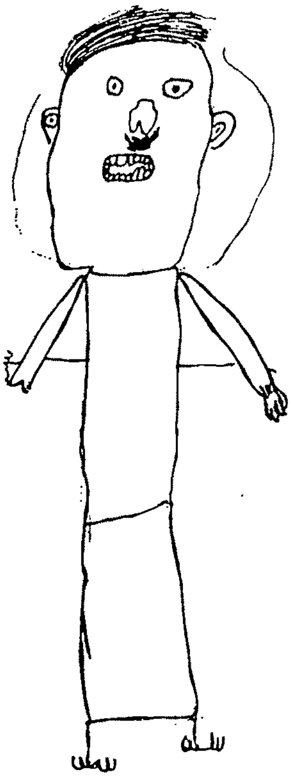
(a) *The picture of a man by a Malay child emphasises the clothing. Note also the car in the background. (IQ equivalent 105).*

(b) *Chinese child has drawn a man with very simple clothing but excellent facial features. (IQ equivalent 124).*



(c) *Tamil child has drawn a less satisfactory man; even allowing for the long robe which is worn by some Indian men.* (*IQ equivalent 79*).

These drawings have been copied by an artist, as the original pencil drawings did not reproduce photographically.

Discussion

Although drawings of the human figure appear to be a valid measure of a child's growth in conceptual complexity (Harris, 1963), there must also be some effects of cultural influences and personality characteristics. This study confirms the work of Sundberg and Ballinger (1968) and of earlier authors in showing that there are influences which invalidate the draw-a-person as a culture-free test. The standard scores for the DAM and DAW tests were lowest in the Tamil children and these differences could not be accounted for by the measured nutritional or social factors. All such measures must be incomplete and the fact that no causative factors have been identified does not mean that they do not exist. It would certainly be important to find why Chinese children from poor socioeconomic backgrounds score so much better than American children on whom the tests were standardised.

Although the factors influencing the scores cannot be identified, there is ample evidence that they exist and differ among the three ethnic groups we studied. The evidence takes two main forms. When the DAM and DAW scores are compared in individual children, more Chinese and Tamil children scored better in the DAM than the DAW. It is possible that the Tamil children were disadvantaged in the DAW as the customary ethnic female dress, the sari, does not promote good scoring in the DAW, but this could not apply to the Chinese children. Nor does it explain why Malay girls showed no difference between DAM and DAW, but Malay boys scored higher in the DAW than the DAM.

The other feature of the DAM is the different features emphasised by the children of different ethnic groups. Malay children tended to score higher on items related to clothing, while Chinese and Tamil children were apparently more aware of facial features and body proportions. It is possible that the response of Malay children was influenced by the traditional Muslim prohibition on portraits of human subjects, even though this prohibition is by no means rigidly observed.

Any speculation about the causes of the differences in overall scores or in the patterns of response would be unwise in view of the lack of factual data. The Hopi Indians have also been shown to exceed DAM norms (Havighurst *et al.*, 1946) and Nepalese children show different patterns of response (Sundberg and Ballinger, 1968), so such variations are obviously not confined to these Malaysian children.

The observed differences in the DAM and DAW tests probably reflect variations in cultural background among the children of different races (Kuttner, 1970). Such variations are likely to affect a child's motivation and performance at school and perhaps in later life. It is currently fashionable to deny the existence of ethnic differences in intellectual skills. However, it would be more realistic to accept that different cultures may have particular strengths and weaknesses, and adjust educational methods and goals to enhance the strengths and compensate for the weaknesses.

We thank Miss Mei Li Li for scoring the drawings and Mrs Dianne Chandler for her assistance.

Vomiting after pyloromyotomy for infantile hypertrophic pyloric stenosis

LEWIS SPITZ

The Children's Hospital, Sheffield

SUMMARY An analysis of the factors which may predispose towards postoperative vomiting after pyloromyotomy for hypertrophic pyloric stenosis was carried out in 72 infants at this hospital. 26 (36%) infants experienced moderate to severe postoperative vomiting of sufficient intensity to cause the postoperative feeding regimen to be modified or interrupted. Only two parameters were found to be of statistical significance. These were the state of the oesophageal mucous membrane on endoscopical examination and the presence of haematemesis in the preoperative period. No evidence for a gastric mucosal lesion could be found. An advanced oesophageal mucosal lesion was found in 30% of patients, and this was the source of the haemorrhage in all 11 in whom haematemesis was noted preoperatively. The stay in hospital was prolonged (8 days) in those infants with troublesome vomiting postoperatively compared with those with lesser problems (3 days).

Vomiting after surgery for infantile hypertrophic pyloric stenosis is common, yet only vague statements about the problem can be found (Benson, 1969; Swenson, 1969; Cook and Rickham, 1978). In well documented analyses the incidence ranges from 65 to 90% (Table 1).

The precise cause of vomiting has been the subject of numerous reviews, and some authors have even attempted to identify those infants particularly at risk of developing troublesome postoperative vomiting. Haberer (1932) stated that most of the infants with postoperative vomiting 'showed blood in their vomitus preoperatively'. He presupposed a gastric mucosal lesion which required time to heal. Guiseffi (1948) noted that infants over 6 weeks tended to have a 'stormy' postoperative course. Terezis *et al.* (1959) identified a 3 to 8 times greater incidence of postoperative vomiting among infants having either preoperative alkalosis or a loss of >1·0 kg from their greatest attained preoperative weight. Unlike Guiseffi, they found that vomiting was more likely in infants aged 2 to 3 weeks than in ones who were older. Bell (1968) found no difference in the incidence of postoperative vomiting between infants with slight and those with gross metabolic disturbances. Schärli and Leditschke (1968) showed that gastric peristaltic activity had stopped 4–6 hours postoperatively, and that activity was depressed for an additional 16–24 hours. They concluded that early and frequent oral feeding during the first postoperative day was illogical and could lead to postoperative vomiting. Schärli *et al.* (1969) further showed that the incidence was unrelated to the duration of symptoms, to the preoperative serum bicarbonate level, or to special postoperative feeding routines. Benson (1971) suggested that postoperative vomiting could be made less likely by adequate preoperative fluid and electrolyte correction, by wide separation of all circular muscle fibres at surgery, and by avoiding oral fluids until 8 hours postoperatively.

Table 1 *Incidence of postoperative vomiting after pyloromyotomy in other series*

Author	*Year*	*No. of cases*	*Incidence of postoperative vomiting (%)*
Hayes and Goldenberg	1957	122	80
Pollock *et al.*	1957	1422	90
Prosser	1965	281	86
Bell	1968	305	69
Schärli *et al.*	1969	300	65

Incomplete pyloromyotomy as a cause of persistent vomiting is rare (Hayes and Goldenberg, 1957; Benson, 1971) and it is generally recommended that secondary pyloromyotomies should be postponed for 2 weeks after the first operation. Contrast radiography is of little help, as the radiological appearance of pyloric stenosis may persist post-

---

LEWIS SPITZ, consultant paediatric surgeon

operatively for several months even if the stenosis has been clinically relieved (Cremin *et al.*, 1973).

Excessive gastric mucus, secondary to diffuse gastritis, has been implicated by many authors (Rickham, 1969; Swenson, 1969; Dodge, 1975; Nixon, 1976; Cook and Rickham, 1978). They recommend gentle gastric washouts with warm normal saline preoperatively in order to evacuate the stomach of excess mucus.

This study was a prospective analysis of a consecutive series of 72 infants with pyloric stenosis at this hospital during a 3-year period 1975–78. The diagnosis was confirmed at operation in all cases.

The patients

The infants were fully assessed preoperatively, and any disturbance of fluid and electrolyte homeostasis or acid-base balance was corrected preoperatively. The stomach was evacuated of milk curds by gentle saline washouts in each. The pyloromyotomy was performed under general endotracheal anaesthesia and under the same anaesthetic an endoscopical examination of the oesophagus and stomach was carried out using the Olympus paediatric oesophagofiberscope, model EP type PA (maximum external diameter 7·2 mm). All the endoscopical examinations were performed by the same observer. A gastric mucosal punch biopsy was taken in 35 patients. No complications from the endoscopical examinations were encountered.

Classification of postoperative vomiting. Four grades of this symptom were recognised.

Grade I (n=10, 14% patients).
No vomiting at all postoperatively.

Grade II. Slight (n=36, 50% patients).
An odd vomit or occasional posset in the first 24–48 hours postoperatively.

Grade III. Moderate (n=14, 19% patients).
More frequent vomiting, sufficient to modify the postoperative feeding regimen.

Grade IV. Severe (n=12, 17% patients).
Excessive vomiting causing prolonged delay in establishing oral nutrition and often necessitating parenteral fluid administration.

The incidence for each grade of postoperative vomiting was assessed according to the following preoperative parameters. (1) Age of the infant on admission. (2) Sex. (3) Duration of symptoms. (4) Birthweight. (5) Degree of weight loss or failure to thrive. (6) Presence of haematemesis. (7) Feeding practice. (8) Size of the pyloric 'tumour'. (9) Appearance of the oesophageal mucosa on endoscopy. (10) Appearance of the gastric mucosa on endoscopy. (11) Presence of alkalosis. (12) Presence of dehydration.

For the purposes of statistical analysis the two grades with slight problems or none were combined (group 1) as were those with moderate and severe postoperative vomiting (group 2). This appeared to be a logical approach as the practical significance of the vomiting was determined by whether or not the postoperative feeding regimen had to be interrupted.

Statistical analyses used consisted of the χ^2 and Student's t tests if appropriate.

Results

Age on admission. The mean age on admission was 5·7 weeks, range 2 to 16. There was no statistically significant difference in the age on admission between the two groups (χ^2 0·9407, P>0·05). It is noteworthy that all 4 infants aged <3 weeks experienced pronounced postoperative feeding problems.

Sex. There were 55 boys and 17 girls in the series (ratio 3 : 1). This ratio was maintained in the various grades of postoperative vomiting.

Duration of symptoms. The mean duration of symptoms before admission was 15 days. There was no correlation between the duration of symptoms and the incidence of postoperative vomiting. (t 1·0309, P>0·05)

Birthweight. The mean birthweight for the 72 patients was 3200 g. There was no significant difference in birthweight between the two groups (t = 1·5480, P>0·05) and this applied equally to those infants weighing <2500 g at birth.

Degree of weight loss. The degree of failure to thrive was determined by measuring the difference between the expected and the actual weight on admission using the standard Tanner and Whitehouse growth chart. Seven infants displayed a positive growth pattern, 2 remained on their original centiles, while the remaining 63 infants failed to thrive. The average decrease in growth for the last group was assessed at −1·03 SDs from the mean. The degree to which infants in the two groups failed to thrive was not of statistical significance (t = 0·437, P>0·05).

Haematemesis. Eleven (15·3%) patients gave a positive history for blood in the vomitus preoperatively, either in the form of frank blood or 'coffee grounds'. Two had slight postoperative vomiting, while the remaining 9 experienced either moderate (7) or severe (2) vomiting. The difference was statistically significant (χ^2 9·5349, P<0·01).

Feeding practice. 24 infants were entirely breast fed while 40 were fed on a variety of proprietory milk formulae. Insufficient data were available in 8 patients. No difference could be determined in the incidence of postoperative vomiting according to feeding practice.

Size of the pyloric 'tumour'. The size of the pyloric tumour was subjectively estimated at operation to be small, moderate, or large (R. B. Zachary, 1975, personal communication). There was no correlation between the size of the 'tumour' and the frequency of postoperative vomiting (χ^2 2·9205, P>0·05).

State of the oesophageal mucous membrane. Endoscopically four types of oesophageal musoca were recognised: Grade 0—normal appearance (32 patients); I—slight erythema of the distal oesophagus only (18 patients); II—erythematous and friable mucosa (10 patients); III—presence of superficial ulceration of the mucous membrane (12 patients).

Analysis of the incidence of postoperative vomiting according to the above criteria is shown in Table 2. Although there was no statistical difference between the individual subgroups, infants with a normal or only slightly erythematous distal oesophagus experienced significantly less postoperative vomiting than those infants with a more advanced oesophageal mucosal lesion (χ^2 18·1983, P<0·001).

State of the gastric mucosa. No infant showed any evidence of a diffuse gastric mucosal lesion either on endoscopy or on histopathological examination of the mucosal biopsy (Batcup and Spitz, 1979). 19 (26%) infants displayed occasional punctate haemorrhages on endoscopy. There was no correlation between presence of punctate haemorrhages and the incidence of postoperative vomiting.

Alkalosis. 24 (33%) infants were biochemically alkalotic, as defined by a serum bicarbonate level preoperatively >28 μmol/l. No correlation could be found with the incidence of postoperative vomiting (χ^2 2·1747, P>0·05).

Table 2 *Degree of oesophagitis in relation to postoperative vomiting*

Oesophageal mucosal inflammation	*Degree of postoperative vomiting*			
	None	*Slight*	*Moderate*	*Severe*
Grade 0	7	20	1	4
I	1	11	4	2
II	1	3	3	3
III	1	2	6	3

Dehydration. There was no relation between the incidence and severity of clinical dehydration (28 patients), or azotaemia (11 patients) and postoperative vomiting (χ^2 0·7533, P>0·05).

Discussion

Of the various parameters analysed only two of statistical significance emerged—namely, the appearance of the oesophageal mucosa on endoscopical examination and the history of haematemesis preoperatively. It is noteworthy that of the 22 infants exhibiting a friable or ulcerated oesophageal mucous membrane on endoscopy, 11 (50%) gave a positive history for blood in the vomitus preoperatively. In view of the absence of evidence for gastritis endoscopically and on pathological examination, it can be concluded that the oesophageal, rather than the gastric mucosa, was the source of the haemorrhage in the infants in this series.

This finding is in direct contrast with the views of most authors on the subject (Benson and Lloyd, 1964; Swenson, 1969; Dodge, 1975; Nixon, 1976; Cook and Rickham, 1978). Forshall (1955) and Roviralta (1967) were the first to recognise the association between lower oesophageal sphincter incompetence and hypertrophic pyloric stenosis. Pellerin *et al.* (1974), in a retrospective study of 627 cases of hypertrophic pyloric stenosis with adequate radiological study of the hiatal region, demonstrated gastro-oesophageal reflux in only 13% of cases. Although it is generally recognised that oesophagitis commonly occurs secondarily to lower oesoghageal sphincter incompetence, the converse may equally apply. Lower oesophageal irritation may adversely affect the competence of the gastro-oesophageal mechanism (Eastwood *et al.*, 1975). Manometric studies of the oesophageal peristaltic activity were not undertaken in this series.

The finding of advanced oesophageal mucosal inflammation in 22 (30%) of the 72 infants, indicates that gastro-oesophageal reflux is more common than had been previously recognised. It has furthermore been shown to be a significant factor in the pathogenesis of postoperative vomiting in infants with hypertrophic pyloric stenosis. The effect of posture on the incidence of postoperative vomiting is currently being studied.

It is not my intention to advocate endoscopy on all infants with pyloric stenosis. The finding of oesophagitis in almost one-third of the infants was unexpected, but it has proved to be relevant with regard to the postoperative management of these infants. A positive history of haematemesis, which has been shown to be a consequence of the oesophagitis, should alert the clinician to the possibility of a complicated postoperative course.

Are the findings of this study relevant to clinical practice? The duration in hospital after pyloromyotomy is an important indicator. The postoperative hospital stay was prolonged in those infants with troublesome vomiting (mean 8·2 days) compared with the group with slight problems and in whom the feeding regimen was able to proceed without interruption (mean 3·6 days). The difference is statistically significant ($t = 6{\cdot}3263$, $P<0{\cdot}001$).

Chronic pericardial constriction with effusion in childhood

G. B. HAYCOCK AND S. C. JORDAN

Bristol Royal Hospital for Sick Children, and the Cardiac Department, Bristol Royal Infirmary

SUMMARY Five cases of children with nontuberculosis pericardial constriction with effusion are reported. The disease is not as rare as had been thought, and the aetiology in these cases was probably a previous virus infection. A previous diagnosis of hepatitis, nephrotic syndrome, or protein-losing enteropathy had been made and the correct diagnosis was delayed for months or even years. Pericardiectomy produced immediate relief from symptoms in 2 patients but in 2 others there was evidence of poor myocardial function postoperatively.

Constrictive pericarditis is rare, particularly in children. Watson (1968) estimated that: 'The disease represents not more than one in 10 000 cases of cardiac disease presenting in childhood in North America at present, but it may play a larger role in other countries particularly where tuberculosis is more prevalent'. The true incidence of the disease cannot accurately be given and it may be a good deal more common than Watson thought, as it is likely that some cases are asymptomatic and others are misdiagnosed. Five cases were seen in children during a 6-year period at the Bristol Royal Hospital, where about 300 new children with cardiac disease are seen annually, an incidence of 1 : 360 such children.

Case reports

Case 1.

History

A girl, born at 38 weeks' gestation birthweight 1820 g, was described as 'always a poor feeder from birth'. At 18 months mild lactose intolerance was diagnosed. She was referred here at 7 years with weight loss and increasing abdominal distension.

Examination

She was small and wasted (height 111 cm, weight 18·1 kg) with conspicuous abdominal distension due to ascites and hepatomegaly. The peripheral circulation was poor, the pulse small volume with obvious reduction in volume in inspiration, 'pulsus paradoxus'. The venous pressure was raised beyond the angle of the jaw. The cardiac impulse was faint and a very loud early diastolic sound was present.

Investigations

Chest *x*-ray showed an increased cardiothoracic ratio, the heart being visible as a separate shadow within the pericardium on one overpenetrated film. The presence of an effusion was confirmed by ultrasound examination. Mantoux test negative. Viral studies, including culture of ascitic fluid, negative.

Treatment

At operation (Mr R. H. R. Belsey), both parietal and visceral pericardium were considerably thickened in a uniform fashion and a sizeable effusion was found. The parietal pericardium was removed from the major part of both ventricles, as well as most of the visceral pericardium. Histology showed thickening and fibrosis, with moderate round cell infiltration.

Progress

Although initially she required antifailure treatment, 8 months later our patient was well and the heart was clinically and radiologically normal.

Case 2.

History

A girl was transferred to this hospital for investigation of hepatomegaly and ascites. She had been born by normal delivery at term. At 6 months she was noted to have bilateral interstitial keratitis. At age

Bristol Royal Hospital for Sick Children, Bristol
S. C. JORDAN, consultant cardiologist
Department of Paediatrics, Guy's Hospital, London
G. B. HAYCOCK, consultant paediatrician

10 months she was admitted for investigation of abdominal swelling.

Examination
Obvious ascites, enlargement of the liver and spleen. Loud early diastolic sound.

Investigations
Chest *x*-ray showed considerable cardiomegaly and the heart shape was consistent with the presence of a pericardial effusion (Fig. 1). Tuberculin test consistently negative. Viral studies negative. Abdominal paracentesis on two occasions showed straw-coloured fluid. Transpleural liver biopsy was normal histologically. Her condition deteriorated after this procedure, and she developed pulsus paradoxus; cardiac tamponade was diagnosed. Pericardiocentesis was therefore performed, 150 ml greenish fluid being obtained, but the signs of tamponade recurred during the next 2 weeks.

Operation (Mr R. H. R. Belsey)
The heart was found to be surrounded by a densely adherent, grossly thickened visceral pericardium which was severely impeding cardiac filling. The parietal pericardium was thickened also, and was removed in its entirety, large portions of the visceral pericardium being dissected off the ventricles and removed also. Histologically the excised tissue showed dense fibrosis with scanty chronic inflammatory cells.

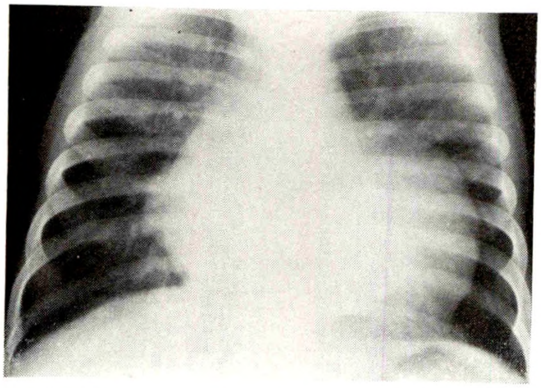

Fig. 1 *Case 2 x-ray. Cardiac shadow is enlarged but a faint medial opacity due to the heart itself is also shown.*

Progress
During the next 7 days large volumes of fluid drained from the left chest drain, but this gradually tailed off and thereafter her postoperative recovery was rapid and uneventful with prompt disappearance of all signs of impaired right heart filling. Five years later she remains perfectly well and the cardiovascular system appears normal.

Case 3.

History
A girl was noted at age 2 years to be breathless and cyanosed on exertion. Medical advice was not sought at that time and she presented at age 8 years with effort dyspnoea and occasional right-sided chest pain on exertion.

Examination
Slight central cyanosis. Small volume pulses. Jugular venous pressure greatly raised, with prominent A- and V-waves. No abnormalities were detected on auscultation. Liver palpable 3 cm below the right costal margin.

Investigations
Chest *x*-ray showed gross cardiomegaly with prominence of the superior vena cava and of the veins of the upper lobes of the lungs. Multiple opacities and septal lines were present at the bases, with a small right-sided pleural effusion. Tuberculin test negative. Antibodies to Q fever, psittacosis, *Mycoplasma*, mumps, and *Toxoplasma gondii* negative. Viral culture in HeLa and monkey kidney cells negative. Cardiac catheterisation (Table).

Operation
A pericardiectomy was performed (Mr G. Keen). The pericardium looked thickened and there was a moderate accumulation of pericardial fluid. Histologically the pericardium was moderately thickened but it was otherwise normal.

Table *Cardiac catheterisation*

Case	*Right atrium (mmHg)*		*Right ventricle (mmHg)*	*Pulmonary artery (mmHg)*		*Wedge (mmHg)*	*Left ventricle (mmHg)*	*A-V O_2 difference*	
	A-wave	*Mean*		*S/D*	*Mean*	*Mean*		*%*	*O_2 content*
3	36	28	100/12/25	100/65	80	26	100/12/25	54	9·6
4	9	8	35/ 6/ 8	33/12	18	12	—	—	—
5	30	25	42/15/25	40/30	32	26	—	39	6·3

Progress
Jugular venous pressure fell almost to normal and she was symptomatically greatly improved, but continued to show mild cardiomegaly and abnormal T-waves in the ECG. She died suddenly 2 years later, presumably from an arrhythmia.

Case 4.

History

A girl born by normal delivery at 38 weeks' gestation, birthweight 3200 g. She was admitted to hospital at age 2 months for investigation of convulsions. A chest *x*-ray showed a cardiothoracic ratio of 0·6, and an ultrasound cardiogram showed a moderate sized pericardial effusion and a small or normal sized heart.

Progress
Radiological signs of pericardial effusion remained for 2 years but then gradually subsided and our patient has since remained well.

Case 5.

History
A 2½-year-old girl was referred to this hospital with a one-year history of lethargy, oedema, and abdominal swelling. She was seen at another hospital and found to have albuminuria, and a tentative diagnosis of nephrotic syndrome was made; later this was changed to active hepatitis and then to protein-losing enteropathy.

Examination
Oedema of legs and face and moderate ascites. Liver 10 cm below the costal margin, jugular veins engorged with no obvious pulsation. A loud, early diastolic sound was audible all over the praecordium.

Investigations
Chest *x*-rays showed an enlarged cardiac shadow. ECG showed right and left atrial hypertrophy, small voltage QRS complexes, and flat T-waves (Fig. 2). Cardiac catheterisation (Table) showed findings

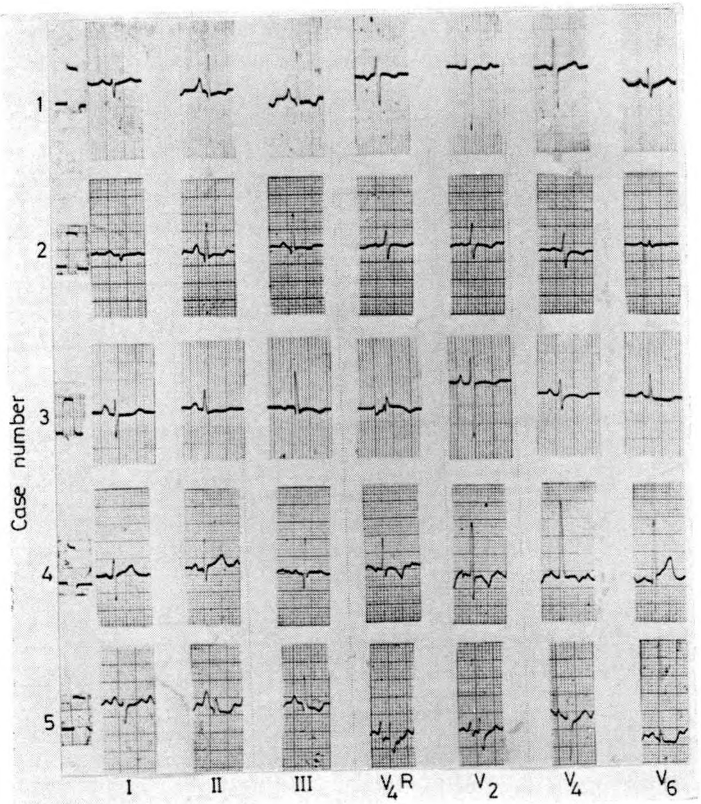

Fig. 2 *Preoperative electrocardiograms of the 5 patients.*

consistent with pericardial constriction, there being a pronounced 'dip and plateau' pattern in the right ventricular trace.

Operation (Mr R. H. R. Belsey)
The parietal pericardium was mildly thickened and distended by a large straw-coloured effusion. There was no adhesion of visceral and parietal pericardium. The pericardium was excised between the phrenic nerves. It was uniformly thickened with moderate numbers of chronic inflammatory cells.

Progress
Postoperatively the patient continued to drain moderate quantities of fluid for 7 days (1·6 litres) through the left pleural drain. After removal of the drain, fluid reaccumulated in the left chest and a further 2·8 litres were removed by repeated paracentesis, but eventually the effusion was controlled by frusemide 20 mg daily. During the next 6 weeks the dose was reduced and she remained well with a normal venous pressure and no abnormal signs. Four months after operation the venous pressure was again raised. The cardiac size on *x*-ray was within normal limits. Repeat cardiac catheterisation still showed equally raised right atrial and pulmonary wedge pressures. The chest was re-explored to exclude recurrent constriction but none was found. Six months later she still required a moderate dose of diuretic (10 mg frusemide daily) to keep her out of failure, and this has continued to do so to date.

Discussion

Aetiology. The 5 cases described have in common the presence of persistent pericardial effusion. This was associated with impaired heart filling in 4 and proved thickening of the pericardium in 3. The aetiology is obscure in all, although in 2 of the children there were associated features which support the suggestion of viral infection. Presumptive evidence for a virus aetiology to explain 'idiopathic' pericardial constriction was produced by Robertson and Arnold (1962) who found a cluster of about 5 such cases a year after an epidemic of virus pericarditis: 2 of their patients had had pericarditis during the epidemic (caused by Coxsackie B5 virus). In our Case 2 the coexistence of interstitial keratitis with negative serology for syphilis, and in Case 1 the low birthweight for gestational age and poor progress from birth, would be consistent with this possibility.

It was usually assumed, before the introduction of effective antituberculous chemotherapy, that tuberculosis accounted for most of the cases diagnosed as constrictive pericarditis. Simcha and Taylor (1971) stated: 'Tuberculosis plays a major role in the aetiology of constrictive pericarditis; strong evidence of this is found in this series'. This claim seems difficult to justify on the basis of their paper since in only one of 5 cases was a diagnosis of tuberculosis well established, and the evidence adduced in favour of this disease in 2 other cases was not convincing. Indeed, some doubt existed about the importance of tuberculosis as the main cause of constrictive pericarditis even before the introduction of streptomycin; of 37 cases (all children) reviewed by Rothstein (1934) tuberculosis was given as the diagnosis in only 9, with one doubtful, the remainder being attributed to rheumatism or 'unknown' in roughly equal proportions. Other authors (Mortensen and Warburg, 1948; Kuipers, 1955; Vining, 1955; Dalton *et al.*, 1956; Shea *et al.*, 1957; Caddell *et al.*, 1960) have presented small series of children, or included the occasional child in series of adults, but in these papers tuberculosis did not feature prominently as a proved cause. Even in countries where tuberculosis is common it probably only accounts for about half the number of cases (Das *et al.*, 1973).

Apart from tuberculosis, a variety of other disease processes have occasionally been found to cause constrictive pericarditis; these include histoplasmosis, Coxsackie pericarditis (particularly strains B3 and B5), traumatic haemopericardium, rheumatoid disease, hydatid disease, myxoedema, amyloidosis, sepsis (for example meningococcal and staphylococcal septicaemia), and malignant disease. Practically all accounts agree, however, that in any sizeable series the majority of cases occur in the absence of any identifiable primary disease, and the known causes, even collectively, constitute the minority (*British Medical Journal*, 1968; Keith *et al.*, 1968; Watson, 1968; Mullen *et al.*, 1969).

The role of acute rheumatism, if any, in the aetiology of constrictive pericarditis is not clear. Simcha and Taylor (1971) regarded it as hardly ever leading to constrictive pericarditis, while Rothstein (1934) attributed 13 of 37 cases to this cause.

Our 5 cases had moderately large, serous effusions, separating parietal and visceral pericardium. This is not generally a feature of tuberculous constrictive pericarditis, but is in keeping with the findings of Harrold (1968) in 3 adults with non-tuberculous pericardial constriction. Cayler *et al.* (1963) found moderately large pericardial effusions in their patients, but each one presented during the course of acute pericarditis.

Diagnosis. Although 2 of our patients presented with short histories and the diagnosis was suspected before referral, the other 3 were clearly undiagnosed for periods of several months or years. The failure to diagnose the presence of pericardial constriction was partly due to failure to notice or realise the significance of the raised venous pressure. If the venous pressure is so high that there is no longer obvious venous pulsation in the neck, the difficulties of assessment are well known. Another factor in the failure to make a diagnosis was the presence of secondary effects of the high venous pressure. Hepatic enlargement with abnormal liver function tests led to a diagnosis of active hepatitis and liver biopsy was performed (a procedure not without risk when the venous pressure is high). Similarly the effect of high venous pressure in the kidneys may cause a secondary nephrotic syndrome. Our Case 5 was similar in this respect to a 58-year-old patient reported by Pastor and Cahn (1960). Case 5 was initially diagnosed as having protein-losing enteropathy and this too has been reported as a complication of pericardial constriction (Plauth *et al.*, 1964).

The auscultatory signs in pericardial constriction are not obvious. Three of our patients had a loud, early diastolic sound, but this is often so early that it is mistaken for the second sound. The ECG is not specific and patients with only a small effusion, or none, may have a remarkably normal looking cardiac size and shape on chest *x*-rays. Diagnostic ultrasound (Feigenbaum *et al.*, 1967) is useful when there is a pericardial effusion.

Treatment. There were clear indications in 4 of our patients for surgical treatment. In one of them treatment was required fairly urgently for rapidly increasing signs of right heart failure and reduced cardiac output. In the other 3 there were obvious indications from the secondary effects of high venous pressure on the liver, kidneys, and gut. The surgeon's aim is to remove the thickened pericardium (visceral as well as parietal if necessary) from more than half the surface of the heart so that any further contraction of the remaining pericardium does not constrict the heart. In 2 of the operated patients the pericardial effusion separated parietal and visceral pericardium. In the other 2 a variable amount of dissection of pericardium from the heart itself was necessary. The exudative nature of the pericarditis is well shown by the 2 patients (Cases 2 and 5) who continued to drain fluid for several days or weeks after pericardiectomy. This was a surprising feature in view of the almost complete lack of signs of inflammation microscopically in the excised pericardium.

Myocardial involvement. Two of our patients (Cases 3 and 5) probably had chronic myocardial damage and Case 1 also showed temporary cardiac failure in the postoperative period. The possible reasons for myocardial involvement were reviewed by Levine (1973). Possible explanations are associated myocardial fibrosis (particularly if a viral aetiology is suspected), and the splinting effect of the constriction preventing the heart from dilating adequately.

We thank Dr J. A. Apley for permission to report Cases 1, 2, and 4 and Dr F. G. M. Ross for carrying out ultrasound cardiograms in Cases 1, 2, 4, and 5.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onwards all manuscripts submitted should accord with the new style.

Short reports

Accuracy of pre- and postnatal assessment of gestational age

DEBORAH MITCHELL

Medical student, Guy's Hospital, London

SUMMARY The gestational age at delivery in a group of 20 neonates was estimated prenatally from measurements of the biparietal diameter made by ultrasound during pregnancy, and postnatally from the newborn infant's neurological and external physical criteria of maturity using the method of Dubowitz *et al.* (1970). These two assessments were compared with the gestational age at delivery calculated from the date of the last menstrual period (LMP) in mothers certain of their dates. Gestational age derived from the ultrasound data correlated well with that derived from the mother's LMP, and much better than did gestational age derived from the postnatal scoring system.

While the date of the last menstrual period (LMP) is accepted as the most accurate assessment of gestational age, provided that the mother is certain of her dates and has a regular cycle, such information is not always available and other methods have been sought. Antenatally, measurement of the biparietal diameter (BPD) of the fetus by ultrasound is increasingly applied as a routine part of antenatal care. Postnatally, physical and neurological criteria of maturity are used to assess the gestational age of the newborn infant, the most thorough method being that of Dubowitz *et al.* (1970). In this study these two methods were used to assess the gestational age at delivery in a group of 20 neonates, and compared with the gestational age calculated from the date of the LMP.

Methods

The neonates examined were singletons in the nurseries of the obstetric wards at Guy's Hospital. They were examined by the same person and scored according to the method of Dubowitz *et al.* (1970). If bilateral signs were different the more mature score was taken. Babies were examined within a few hours of birth. The results were not separated into male and female infants as it has been shown by Parkin *et al.* (1976) that there is no significant difference between their scores.

Information about the date of the LMP was collected from the antenatal notes by persons other than the examiner, and not seen by the examiner until all the neonates in the study had been seen and scored. Cases where the LMP was a withdrawal bleed from the pill rather than a true period were excluded from the study.

The estimated date of delivery was calculated from the LMP by adding on 280 days.

BPD measurements were obtained from the ultrasound department records, and the gestational age at the time of measurement read off from the cephalometry chart compiled by Campbell and Newman (1971), the gestational age at delivery being estimated by adding on the appropriate number of days. Only those infants who had had ultrasound measurements taken before 30 weeks' gestation were included, as Lunt and Chard (1974) showed that there is an increasing error in the measurement of BPD after 31 weeks. In most babies ultrasound measurements were made between 20 and 24 weeks, in one infant at

18	38	38·5	38
19	38·5	40·5	42
20	39	41	39·5

between 27 and 29 weeks, and in two between 16 and 20 weeks.

Results

The correlation coefficient for the ultrasound BPD and LMP estimations of gestational age was +0·8837, P<0·0005. The correlation coefficient for the Dubowitz scoring system and LMP estimations of gestational age was +0·4128, P<0·05 (Table).

Discussion

When the gestational age estimated by these two methods was compared with that estimated from the date of the LMP of mothers certain of their dates, the estimation using ultrasound data correlated much more closely with that derived from the LMP than did that using the method of Dubowitz *et al.* (1970). Thus when accurate LMP data are not available, the most reliable method of assessing the gestational age is by ultrasound BPD measurement early in pregnancy. The superiority of the ultrasound method is particularly relevant in the case of sick neonates; these should be handled as little as possible and will therefore be assessed on external criteria only, although less accurate than the method of Dubowitz *et al.* (1970) which comprises neurological as well as external physical criteria.

I thank Dr B. King for information from the ultrasound department, Hilary Noakes who made the BPD measurements, Dr El Bishti for help with the statistics, and Professor R. J. Robinson for advice and encouragement.

Breast milk and breast feeding in very low birthweight infants

J. L. PEARCE AND L. F. BUCHANAN

Department of Paediatrics, Taranaki Base Hospital, New Plymouth, New Zealand

SUMMARY The feeding of 17 babies weighing <1500 g was examined retrospectively. 12 babies started breast feeding at a mean weight of 1324 g and 10 of them were fully breast fed by a mean weight of 1600 g. Their weight gains were comparable with bottle-fed babies receiving expressed breast milk. Practical aspects of breast feeding were considered to be: a knowledgeable maternal and nursing attitude, close mother and baby contact, early expression of breast milk, and early suckling. The increased incidence of breast feeding by mothers of both low birthweight and term babies ensures regular supplies of fresh breast milk. Therefore, sterilisation or storage of breast milk here is unnecessary.

Interest in feeding low birthweight infants has been revived by numerous scientific analyses of the properties of breast milk (*British Medical Journal*, 1978). Many papers are preoccupied with differences between treated and raw breast milk, and with the storage of milk in banks (Ford *et al.*, 1977; Evans *et al.*, 1978; Williamson *et al.*, 1978). While tube feeding will inevitably be required in the management of very low birthweight babies, there is a danger that the ability of babies to suckle at the breast will be ignored and there are few studies on this aspect. Very low birthweight babies are usually the most difficult ones to feed. We therefore report on the management of the last 17 consecutive babies born in this unit weighing <1500 g, with particular reference to breast feeding.

Materials and methods

The babies weighed between 750 and 1500 g (mean 1272 ± 190 SD) and 13 were appropriate for gestational age. All babies were managed in a neonatal unit. Major complications were encountered by 2 babies who required ventilation, and 3 who required continuous positive airways pressure for respiratory distress syndrome or apnoea. 14 babies received IV fluids for a mean period of 3½ days. No other parenteral alimentation was given. The babies received 800 units vitamin D and 60 mg vitamin C daily after feeds were begun.

All babies were fed by a standard regimen of intermittent gastric gavage if their condition permitted. Breast or bottle feeding was started when sucking movements were noted. Gavage feeding was continued according to the success of breast feeding and satisfactory weight gain.

All low birthweight babies in this unit are fed expressed breast milk. Milk is manually expressed or allowed to ejaculate into sterile bowls and refrigerated. It is not boiled or frozen and is discarded after 24 hours. Milk was donated by mothers of babies in the neonatal unit and in the postnatal maternity ward. Mothers were asked about breast feeding within a few hours of birth and encouraged to express milk, particularly colostrum, to feed their babies. They were encouraged to assist with gavage feeding. Babies who were breast fed did not receive bottle feeds.

Weight gains of all babies were plotted on standard growth grids (Dancis *et al.*, 1948) and growth of head and length was recorded.

Results

12 babies started breast feeding at a mean weight of 1324 ± 99 g SD, and mean age of 11 days. The 10 babies who were successful were fully breast fed by a mean weight of 1600 ± 139 g, and a mean age of 27 days. All the breast milk for these babies was provided by their mothers from the 2nd or 3rd day postpartum. Of the 2 mothers who failed, one had waited for 30 days before starting breast feeds and was unable to keep lactating, the other fed for 5 weeks and gave up for 'convenience' just before discharge. Complete breast feeding usually coincided with stable temperature control and the babies were discharged at a mean weight of 1677 ± 104 g. Mean weekly weight gains for the 11 babies who were breast fed in the neonatal period are given in the Table. A transient slowing of weight gain after withdrawal of supplementary milk was common.

Table *Weekly weight gains (mean ± 1 SD) of breast- and bottle-fed babies*

	Weeks			
	1	*2*	*3*	*4*
Breast fed (g)	−82 ± 79	141 ± 40	148 ± 41	134 ± 73
Bottle fed (g)	−89 ± 59	133 ± 35	134 ± 81	159 ± 50

The amount of supplementary milk given to these babies was too variable to tabulate. The parents of these babies were white; one was unmarried.

The weight gains of the 6 babies given untreated expressed breast milk by bottle were comparable with those breast fed (Table). Of the mothers of these babies, 5 were of mixed blood (Maori, Indian, and European) and 5 were unmarried.

Discussion

This study shows that very low birthweight babies can be breast fed early. The mean weight and small standard deviation at which babies started breast feeding suggests that they are mature enough to suckle when they are about 1300 g. There were no complications attributed to early breast feeding. Successful breast feeding, particularly of very low birthweight babies, is attributed to many factors: unrestricted visiting of mother and family to the neonatal unit, an optimistic and knowledgeable attitude of the nursing staff to breast feeding, and babies to be breast fed being virtually never bottle fed. The problem of maintaining maternal milk secretion is paramount. Manual or hand pump expression of milk was used and we have no experience with mechanical breast pumps. On occasions, mothers breast fed other babies to stimulate milk secretion. Breast feeding a very low birthweight baby demands tremendous maternal commitment and co-operation, often for long periods. It is therefore essential to provide facilities for mothers to stay beside the neonatal unit without the usual hospital restrictions.

As would be expected, the main factor against breast feeding was maternal disinclination, strongly associated with sociological and racial factors.

Untreated expressed breast milk and breast feeding produced adequate weight gains in this small group of very low birthweight babies as judged from the weight grids used. Weight grids that are derived from cows' milk-fed low birthweight babies can, at best, only provide reference points. Optimum weight gains are unknown. The advantages of breast milk over cows' milk substitutes have been reviewed elsewhere (Addy, 1976; Jelliffe and Jelliffe, 1977). The use of untreated breast milk appears safe (Hack *et al.*, 1975) and probably preserves the antibacterial properties which are reduced by most methods of sterilisation (Ford *et al.*, 1977; Evans *et al.*, 1978).

The availability of milk has increased in recent years with the trend towards breast feeding. Therefore, in this region, storage of milk in banks is unnecessary. The present emphasis on milk storage and sterilisation is misplaced. The emphasis should be on educating and encouraging mothers to breast feed their own babies. A high rate of breast feeding in neonatal units and postnatal wards will ensure a ready supply of fresh expressed breast milk.

Is it necessary to warm infants' feeds?

C. COSTALOS, I. ROSS, A. G. M. CAMPBELL, AND M. SOFI

Department of Child Health and Department of Chemical Pathology, University of Aberdeen, Scotland

SUMMARY The effect of temperature on gastric emptying after milk feeds was studied in 31 newborn infants. Test meals were a commercially prepared modified cows' milk (a) at body temperature and (b) at room temperature. Our results suggest that temperature has no effect on gastric emptying.

Before feeding a baby it is customary to warm the milk to approximately body temperature. This time-consuming procedure is presumably designed to mimic breast feeding as closely as possible. Even today when prepacked feeds are widely used, most mothers prefer to warm their babies' feeds, often using bottle-warmers which may be a fire hazard and a source of infection. Because food temperature has been shown to influence the rate of gastric emptying in adults (Ritschel and Erni, 1977) we decided to study the effect of feed temperature on gastric emptying in the newborn period.

Methods and infants

31 infants born in Aberdeen Maternity Hospital were studied. Their characteristics are shown in the Table. All the babies were being fed routinely via indwelling polyvinyl nasogastric tubes every 4 hours. The method of serial test meals used for adults (Hunt, 1951) had been modified for studying gastric emptying in the newborn (Husband and Husband, 1969). Initially the stomach was washed out with

water until free of large curds. Test meals (20 ml/kg) were given 3 hours after the last feed and over a period of 3–4 minutes. After an interval of 30 minutes the gastric content was aspirated. The stomach was then washed out with 20 ml water to recover any remaining feed.

Test meals consisted of modified cows' milk formula (SMA Gold Cap) (a) at body temperature (37°C); (b) at room temperature (24°C). Phenol-red 0·24 mg/100 ml as a marker was added to these meals as it is not absorbed from the stomach and has no effect on gastric emptying (Hunt, 1956). Specimens obtained were kept frozen (−4°C) until analysed. Details of the calculations for estimating the gastric emptying rate are shown in the Appendix.

Both test feeds were given on the same day after two consecutive routine feeds. Each infant acted as his own control. Infants were nursed prone throughout the test.

Results

The results of the test meals are shown in the Table and Figure. A mean of 61·72% (± 1·86 SEM) of the meal was recovered after the 'warm' feed while the mean for the 'cold' milk was 62·10% (± 2·38 SEM). When these results were analysed by the Student's *t* test for pairs the difference was not significant ($t = 0{\cdot}14$; $P>0{\cdot}5$).

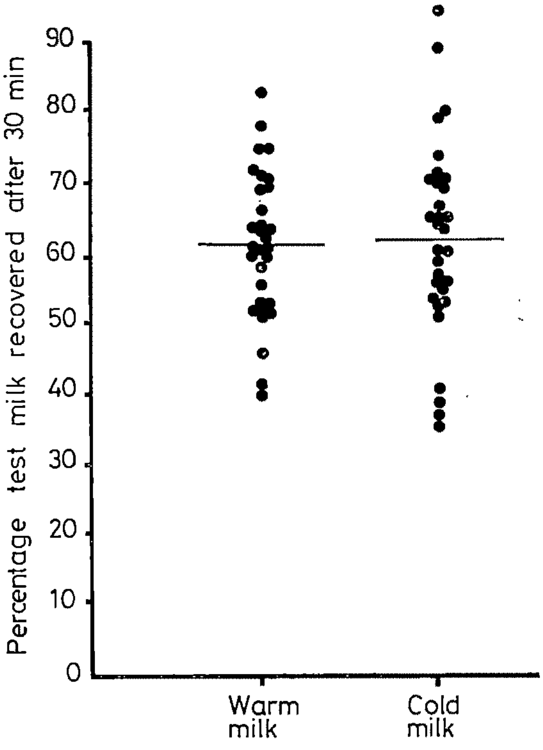

Figure *Percentage of test meal recovered 30 minutes after a milk formula given (a) at body temperature (37°C) (b) room temperature (24°C). Means for the solutions are shown,*

Discussion

Although it is traditional to warm a baby's milk before feeding there have been several trials with cold milk. Gibson (1958) gave 150 infants cold feeds from the refrigerator (4°C) and most accepted them without difficulty. Other studies investigated cold milk for feeding premature babies and no differences were observed in sleep patterns, vocalisations, motility, food or fluid intake, weight gain, or amount of regurgitation when compared with babies fed on warmed feeds (Holt *et al.*, 1962; Illingworth, 1972).

As these studies were based largely on clinical observations, it seemed reasonable to study the effect on gastric emptying as one physiological function which might have been altered by such a variation in feeding. Our results indicate that temperature changes within these relatively narrow limits have no effect on gastric emptying, unlike those of Ritschel and Erni (1977) and Erni and Ritschel (1977) who reported that an increase in temperature prolongs stomach emptying time. There are differences, however, between their methods and ours. The first study (Ritschel and Erni, 1977) was done on adult volunteers, and gastric emptying was studied using a Heidelberg capsule. Test meal consisted of water given at 4–6°C, 20–25°C, or 45°C. The second study (Erni and Ritschel, 1977) was done on rats. James (1957) supported the views of these authors, but did not present any further evidence.

Our failure to demonstrate any difference between feeds administered at room temperature and feeds given at body temperature might reflect the fact that the temperatures selected were not sufficiently different to have any effect. Gastric emptying time may be different after refrigerated milk, but in hospitals that use prepacked milk stored at room temperature there seems to be no advantage in warming the feeds to body temperature.

Appendix

Methods for estimating gastric emptying. The volume of the meal which is still in the stomach can be calculated from the total gastric content recovered, independent of added gastric secretions and saliva, by measuring the concentration of phenol-red (Hunt and Knox, 1962). A 10 ml aliquot of the liquid to be measured was pipetted into a test-tube. 1 ml of concentrated sulphuric acid was carefully

Example: Case 1 in the Table.

	Volume (ml)	*Optical density*
(a) Test meal	30	0·195
(b) Aspirate at 30 minutes	16	0·18
(c) Washout	21	0·01

Vol. of meal in (b) = (16 × 0·18 ÷ 0·195 = 14·76 ml
Vol. of meal in (c) = (21 × 0·01 ÷ 0·195 = 1·07 ml
Vol. of meal remaining in stomach at 30 min = 14·76 + 1·07 = 15·83 ml. % retention of meal at 30 min = 15·83/30 × 100 = 52·76%.

added drop by drop with shaking. It is important to add this acid slowly and to mix carefully to avoid charring the sample. When the whole ml of acid was added the tube was capped and thoroughly shaken and then allowed to stand for about 10 minutes. The acidified sample (pH approx. 1) was then filtered through filter paper no. 42. The clear filtrate was measured in a Vitatron colorimeter using a filter of 510 μm. The machine was put back to zero on water between each sample reading.

Approval for the study of gastric emptying in newborn infants was obtained from the Grampian Health Board, and University of Aberdeen Joint Ethical Committee.

We thank Dr G. Hems for statistical analysis of our results, and Miss Gordon of the Pharmacy Department, Royal Aberdeen Children's Hospital.

Hepatitis A and Indian childhood cirrhosis

S. S. AGARWAL, U. C. LAHORI, S. K. MEHTA, P. C. BAJPAI, B. WERNER, AND D. W. BRADLEY

King George's Medical College, Lucknow, India, Institute for Cancer Research, Philadelphia, USA, and Hepatitis Laboratories Division of Bureau of Epidemiology, Phoenix, Arizona, USA

SUMMARY Antibody to hepatitis A virus (anti-HAV) was found in 50% of patients with Indian childhood cirrhosis; this was not significantly different from the prevalence of anti-HAV in age- and sex-matched controls.

Indian childhood cirrhosis (ICC) is an important cause of mortality in young children in India (Indian Council of Medical Research Liver Diseases Sub-committee, 1955) but its aetiology has remained obscure (Nayak and Ramalingaswami, 1975). It has been suggested that the disease may be a sequel to infection with the virus of viral hepatitis (Achar *et al.*, 1960), but this has been questioned (Nayak *et al.*, 1972). Studies of hepatitis B surface antigen (HBsAG) in patients with ICC have not been conclusive (Chandra, 1970; Nayak *et al.*, 1975). In our experience, evidence of infection with hepatitis B virus can be found in 33% of patients with ICC. HBsAg was found by radioimmunoassay to be present in 18·8% of patients with ICC, and in another 14·2% patients, anti-HBsAg or HBc, or both, could be detected. Although this incidence is significantly higher than in control populations, infection with hepatitis B cannot account for all cases of ICC. Tests for the diagnosis of infection with hepatitis A virus are now available (Bradley *et al.*, 1977), and sera from patients with ICC were, therefore, tested for antibodies to hepatitis A virus (anti-HAV) by radioimmunoassay.

Materials and methods

The serum samples from patients with ICC and controls were collected during 1971–73 at the Children's Hospital, King George's Medical College, Lucknow. The clinical diagnosis and staging of ICC were made according to the criteria adopted from the report of the Indian Council of Medical Research Liver Diseases Sub-committee (1955). The sera were kept frozen at −20°C. Control studies have shown that anti-HAV is stable under these conditions.

Anti-HAV was measured by radioimmunoassay, as described by Bradley *et al.* (1977), in the hepatitis laboratories at the Center for Disease Control, Phoenix, Arizona. In this assay a ratio of equal to, or greater than, 2·1 between the test sample (P) and negative (N) sample (P/N ratio) was considered positive for anti-HAV.

Results and discussion

A total of 50% of the patients with ICC were positive for anti-HAV (Table 1). This number, however, was not significantly different from the prevalence of antibody in age-matched children who were admitted to the hospital for various illnesses other than those of the liver (Table 2). Although the prevalence of anti-HAV was higher in patients with stage I and stage II ICC than in those with stage III disease, the difference was not significant. There were also no great differences in the age distribution of patients in the three stages of the disease. The average P/N ratio for anti-HAV in patients with ICC was 14·6 ± 9·1 SD (range 3·1–31·3) and that in controls was 12·1 ± 8·3 (range 2·3–32·4).

In an endemic area the acquisition of antibody to an infectious agent is a function of age. This is clearly demonstrated by the age-related prevalence of anti-HAV in the patients with ICC as well as in their age-matched controls (Table 2). The prevalance of anti-HAV was no higher for ICC patients between birth and 2 years (42%) than in an age-matched control population (47%). These results do not support an aetiolcgical relationship of hepatitis A to ICC. However, the possibility that ICC may result from an abnormal response to infection with the virus of hepatitis A cannot be excluded. Determination of anti-HAV in serial serum specimens from patients with ICC may help to resolve this issue.

Table 2 *Antibody to hepatitis A virus in relation to age*

Age group (months)	*Patients with ICC*		*Children with diseases other than those of liver admitted to hospital**	
	Tested	*No. (%)*	*Tested*	*Positive No. (%)*
0–12	6	2 (33)	6	1 (17)

Should we follow up children with Henoch-Schönlein syndrome?

J. C. COAKLEY AND T. L. CHAMBERS

Derbyshire Children's Hospital, Derby

SUMMARY We reviewed 31 children who had had Henoch-Schönlein syndrome without nephritis at least 5 years before. None was found to have progressive renal disease and these patients do not require the same long-term follow-up as those with clinical renal involvement.

Although there may be relapses of the abdominal pain, arthralgia, and rash of the Henoch-Schönlein syndrome (HSS) it is the degree of glomerular involvement which determines the long-term morbidity and mortality. About 70% of children have nephritis (haematuria or proteinuria) at presentation (Meadow, 1978) but evidence of renal involvement can be found by more elaborate investigations in most patients. In a few patients with HSS/nephritis the glomerular disease may progress to renal failure: we wondered if a similar deterioration could occur in those without clinical nephritis initially.

Patients, methods, and results

We reviewed the records of 79 patients who had presented with HSS before 1972 and found 52 without haematuria, proteinuria, or urinary casts on at least one occasion during the acute phase of the illness. 31 (19 boys and 12 girls) attended for re-examination: their course at presentation was no different from the nonattenders. The average age of onset of HSS was 5 years (range 7 months to 12 years 5 months), and at review was 12 years 7 months (8 years 4 months to 20 years 5 months) after an average interval of 7 years 11 months (4 years 5 months to 11 years 1 month). A medical history and blood pressure measurement were obtained, and the urine was examined microscopically for cells and casts and by dipsticks for blood and albumin.

Two patients, 8 and 9 years after HSS, had had periodic painless swelling of their knees which was thought to be of musculoskeletal origin rather than a persistent arthritis. The blood pressure was normal in all and urine normal in 28 of the 31 patients. Three boys who were otherwise normal had proteinuria which was transient in 2 and persistent in one (Table).

Discussion

The nephritis of HSS varies in its presentation from being asymptomatic to a rapidly progressive glomerulonephritis. Careful follow-up has shown that although in most patients the nephritis heals, in a few it does not. Of 88 patients followed up for more than 6½ years, 18 (20%) had progressive renal disease (Counahan *et al.*, 1977). Three of these patients who were normal at a 2-year follow-up now had more than 1 g proteinuria per day (1) or hypertension (2), while 6 patients with minor urinary abnormalities 2 years after HSS later showed heavy

Table *Details of 3 cases of Henoch-Schönlein syndrome with urine abnormalities at follow-up*

Case	*Age of onset (years)*	*Symptoms of acute disease*	*Age at review (years)*	*Blood pressure (mmHg)*	*Abnormality*
1	3·0	R, SS, AP, AR	10·5	80/40	+Proteinuria on 2 tests, 24-hour protein <0·1 g
2	5·0	R, AP, AR	15·0	105/60	+++Proteinuria on 1 test, trace on 1 test, 24-hour protein 0·3 g (7 mg/m^2 per hour). Further investigations refused
3	0·7	R, AR	9·9	100/60	Trace proteinuria on 1 test, negative on 2 further tests

R = rash, AP = abdominal pain, AR = arthritis, SS = scrotal swelling.

proteinuria (3), renal insufficiency (2), or hypertension (1). Focal proliferative glomerulonephritis with renal insufficiency (Meadow *et al.*, 1972), and temporary hypertension (Du Bois, 1969), have been reported in children with HSS and normal urinary sediment at presentation of the rash. Abnormal renal histology has been found in children with normal urine at onset of HSS (Greifer *et al.*, 1966) and it is likely that transient haematuria or proteinuria may be missed by once- or twice-daily urine tests. It therefore seemed possible that a few children thought not to have nephritis initially might deteriorate in the same way as the few with nephritis and show signs of renal disease at follow-up. If so, this might also explain the cause of some renal disease and hypertension in adults. The results of this study do not support this; they suggest that the prolonged follow-up of at least 5 years which is recommended for children with HSS/nephritis is unnecessary for those with normal urine at the onset of the rash.

We are grateful to Dr S. R. Meadow for reviewing the manuscript, Mrs V. Sessions and Mrs J. Gray for obtaining records, and Mrs J. Jordan for the typing.

Mourning by the family after a stillbirth or neonatal death

Sir,

In his article (*Archives*, 1979, **54**, 303), Dr Lewis suggested that mourning a stillborn child is facilitated by concentrating on the dead baby, and that an identity is created for the baby by the parents seeing and holding him, talking to the staff, and having a funeral and known burial place for him. Dr Lewis makes little of the more important and positive stages in the baby's development when he is alive and kicking *in utero*, very much existing and far from a nonperson, with both parents enjoying the pregnancy and the planning. It seems extraordinary to replace the memories of these stages, during which parents and the developing if unseen baby have a relationship, with those of a dead, cold, still, and possibly deformed baby. Even the baby of an early miscarriage may live long enough to be thought of as a person; more so is a baby who may have had as long as 20 weeks' visible and palpable activity. Occasionally the parents know before delivery that the baby has an abnormality incompatible with life; however this may not destroy the relationship although it must colour it. It is hard to see what the parents gain by substituting happy memories with ones which are at best negative and at worst shocking. While a funeral for a baby who has lived postnatally is important, it may do little for the parents of a stillborn child. We appreciate that Dr Lewis is looking for ways of making mourning easier for parents, but there is no room for dogmatism. A flexible approach is needed by all members of staff with the senior ones seeing that the conspiracy of silence, which he rightly condemns, is replaced by talking freely both in hospital and later at home.

JANE M. CURRIE AND SIMON CURRIE,
St James's University Hospital,
Beckett Street,
Leeds LS9 7TF

Dr Lewis comments:

Drs Jane Currie and Simon Currie reasonably wonder why I make little of parents' experiences of their babies *in utero*. In consultations with parents we do get them to relive these experiences, but they alone are not enough to facilitate mourning. Although a mother may have generally good feelings about her fetus, her ideas about its identity are necessarily poorly defined. This leaves room for much to go wrong. For instance, if parents have little sense of the personality of their stillborn baby, then the often quick replacement pregnancy, which itself tends to inhibit mourning, can be experienced as a continuation of the previous pregnancy. Then the newborn baby tends to be confused with the stillborn baby. This child may have a muddled sense of identity, suffer from a replacement child syndrome (Poznanski, 1972), or may be a victim of child abuse (Lewis, 1979).

As to contact with the dead baby being negative and shocking, fantasies reported by parents who have not seen their stillborn child are worse than the reality. Parents who have seen their stillborn child, including malformed babies. find relief in doing so and some treasure the experience.

Unfortunately, the psychological experience of stillbirth makes 'talking freely' rather difficult. GPs have been shown to have a strong reluctance to know, notice, or remember anything about a patient who has had a stillbirth (Bourne, 1968). Because a stillbirth is a void, a nonevent, it is difficult to think about, and it cannot occupy a potential thinking space in our minds. It is as if our very painful but vague thoughts about stillbirth occupy a wasteland, a black hole in the mind. Thus stillbirth is an empty drama that takes place at the interface of life and death: there is no catharsis. The experience of having made a baby tends to be annihilated by the experience of stillbirth. We encourage this annihilation by failing to acknowledge the stillbirth as having existed if we deny it a funeral.

The Curries, so keen to recognise the experience of the live fetus *in utero* as important, engage in doublethink when they feel a funeral for a stillbirth could 'do little' for the parents of the stillbirth. To the parents the baby does not cease to be important just because it hasn't breathed. Funerals are our society's way of marking the significance of death. A flexible approach sounds fine. Unfortunately, for the parents of a stillborn child, it often stands for unthinking inactivity, avoidance, and silence.

Congenital absence of the sternum

Sir,

In the last few months we have seen 2 cases of congenital absence of the sternum in the newborn (as opposed to failure of fusion). There was no evidence of ectopia cordis nor was there any other congenital abnormality. A very detailed search for an aetiology was made but no cause could be found except for the fact that both the infants were born to mothers who came from south eastern Saudi Arabia where the diet is very deficient in vitamins, and both mothers had clinical evidence of panhypovitaminosis.

We think that this congenital abnormality in the infants may be due to chronic maternal riboflavine deficiency, as reported by Warkany and Nelson (1941) in experimental animals. Could I, through your columns, ask other paediatricians if they have come across this abnormality, and, if so, what was its aetiology?

Acute inflammatory bowel disease in childhood: a new disease?

Sir,

We should like to report on the subsequent progress of the child described as Case 1 in the paper by Manuel *et al.* (*Archives*, 1978, **53**, 642).

This 6-year-old boy made a complete recovery after his initial illness and remained well for the next 2½ years. He then had an acute episode of diarrhoea and vomiting requiring no specific treatment, but the anorexia and diarrhoea persisted for 2 weeks. Six weeks later he became constipated. This did not respond to treatment with laxatives nor did it respond to repeated enemata over the next 4 months. He also began to have abdominal pains, which were thought to be due to his severe constipation, and he developed painful anal fissures.

Physical examination at this time showed no abnormality apart from a rather scarred anus with two fissures, but colonoscopy revealed scattered aphthoid ulcers throughout the colon characteristic of Crohn's disease, and an ulcerated terminal ileum.

The typical noncaseating granulomata, found in Crohn's disease, were present in the biopsies from the terminal ileum, confirming this diagnosis. He was started on sulphasalazine. He responded satisfactorily, with return of his stools to normal, disappearance of his abdominal pain, and healing of the anal fissures. He has since remained well.

It is interesting to speculate what relationship the initial illness reported in the *Archives* may have had to the subsequent one. Was this an acute presentation of Crohn's disease? This was considered at that time as it is rare to have a diarrhoeal illness of such severity in a child 6 years of age in this country. However at that time none of the usual diagnostic features of Crohn's disease was present—namely the barium follow-through examination did not suggest Crohn's disease, and the abnormality on small intestinal biospy was severe but nonspecific, with an acute inflammatory cell reaction. Was the initial illness in fact a severe attack of acute gastroenteritis which, in some way, has precipitated the development of Crohn's disease in a susceptible individual? The answer to these questions is uncertain, and it remains quite possible that the two illnesses were unrelated. Nevertheless this case illustrates that although spontaneous resolutions can occur in acute inflammatory bowel disease for which no cause has been found, the eventual diagnosis of chronic inflammatory bowel disease is not thereby excluded, and long-term follow-up is necessary in children in whom this diagnosis is made.

Book reviews

Pediatric Surgery. Third edition, in two volumes. Edited by M. M. Ravitch, K. J. Welch, C. D. Benson, E. Aberdeen, and J. G. Randolph. (Pp. 760 (volume 1), 862 (volume 2); illustrated + tables. £135.00 hardback (2 volumes cased). YB Medical Publishers: Chicago. 1979.

This book, the most comprehensive on the subject, is widely respected throughout the world and this 3rd edition maintains this high standard. Two of the 5 editors for this edition are new, as are two-thirds of the 152 authors. The result is that the current edition has been extensively revised and changed. 85% of the authors are from the USA and, with those from Canada, this gives the book some North American bias. As paediatric surgical problems are similar throughout the world this does not detract from the high international standing of the book. The content is wide ranging. It starts with a general section in which genetics, naesthesia, intensive care, and general spects of management are considered. Next trauma in a broad sense is discussed, rom nonaccidental injury with all the sual injuries to less common ones—such s snake and spider bites. In the remaining wo sections the head and neck, and horax and cardiovascular system are discussed. Vol. 2 is divided into sections hat deal with the abdomen, the genito-urinary system, the integument and musculoskeletal system and, finally, the nervous system.

One addition which seems to contribute little to the book is that of some colour lates, but apart from these, the illustrations and presentation are of a high tandard. In a work of this size it is nevitable that there will be an occasional detail which escapes the editors—such as he omission of duplications in the index despite a chapter on duplications) or the mission of any discussion on hypertension in neuroblastoma (despite two earlier references to this). The only facet which does not seem to have adequate cognition is the use of diagnostic ltrasound, despite the considerable dvances achieved with this technique. However the editors must be congratulated on the very high standard they and the authors have set and maintained.

No unit undertaking paediatric surgery should do without this book, although its cost may make some units think twice before purchasing. The investment will be worth while.

D. G. YOUNG

Pediatric Trauma. Edited by R. J. Touloukian. (Pp. 646; illustrated + tables. £24.95 hardback.) Wiley: Chichester. 1978.

This book with its 22 collaborators, all widely known in paediatric surgery, aims to describe in detail the special factors in the care of the injured child from the time he or she is first picked up at the site of the accident. These are: transport, resuscitation, diagnosis, anaesthesia, operation, postoperative management, and rehabilitation.

Accidents are so common in childhood that a good book of this type is always worth having. In the first part there is detailed description of the psychological effects of injury, of anaesthesia and resuscitation, birth injuries and battering, while in the second part, injuries of the organ systems are dealt with in detail and the diagnosis of management in each system is well described. A surgeon might be forgiven for questioning whether the properly trained paediatrician should assume the role of team captain, as is suggested in the preface to this book, and while some minor injuries may be treated by a physician without the help of a surgeon, many of the major injuries described in this book depend on good surgical management and perhaps it is not too old-fashioned to hope that the surgeon should be called in and that he will even be among the first to see the patient.

There is an excellent chapter on evaluation and initial management which could be read with profit by anyone who deals with injured children. This is an excellent book and, unlike some which have purported to deal with injuries in childhood, this one really does. It also sticks to the problems of the child rather than slipping in little bits of adult surgery here and there. There are many good line drawings and indeed some of these are much better than the photographs. There are good and extensive lists of references at the end of each chapter. This book can be recommended as a good guide for those who need help in the treatment of the injured child. It should be in any hospital which treats children.

A. W. WILKINSON

Spinal Muscular Atrophy: Infantile and Juvenile Type. Edited by Irena Hausmanowa-Petrusewicz. (Pp. 180; illustrated + tables. $9 North America; $18 foreign, hardback.) National Center for Scientific, Technical, and Economic Information: Warsaw. 1978. (Available from US Department of Commerce, National Technical Information Service, Springfield, Virginia 22161, USA).

This valuable monograph is based on the rich experience of the Department of Neurology, Warsaw School of Medicine.

It is divided into 14 chapters that cover history, clinical features, classification, morphology, electrophysiology, radiology, psychology, biochemistry, immunology, differential diagnosis, prognosis, genetics, and treatment. The author's experience is compared with that of other workers. There are 521 references and the many pathological illustrations show clearly the changes detailed in their captions. The translation is excellent.

The Warsaw classification of these disorders differs from that more widely used, but the relationship between their type Ia cases (classical Werdnig-Hoffmann disease), type Ib (protracted cases of Werdnig-Hoffmann), type II (intermediate between these two extremes), and type III (Kugelberg-Welander disease) is clearly stated. The total of 310 cases is made up of 79, 77, 59, and 95 respectively in these four categories.

The muscle biopsies are compared with control biopsies from young children (from another source). Muscle cells from affected children show a morphological resemblance to fetal muscle, and this, with a fetal-type muscle protein pattern and the interesting electrophysiological finding in Werdnig-Hoffmann disease of initially slow peripheral nerve conduction velocity, which later becomes normal, suggests that spinal muscular atrophy may be due to persistence of fetal features. This hypothesis suggests that the difference between the various clinical types depends on the number of fibres affected during fetal life, and the stage of fetal development when the presumed insult responsible occurs.

The section on prognosis is very brief and I was disappointed not to find more information based on the large number of cases.

The chapter on treatment is necessari short, but it is interesting to read of therapeutic approach with vigoro exercise in the group III patients.

This is an important book for all wl are interested in these disorders.

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751; 1978, **53**, 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1**, 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. From January 1980 the subscription rate will be £29.00 in the United Kingdom and the Republic of Ireland, and US $70.00 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $70.00, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

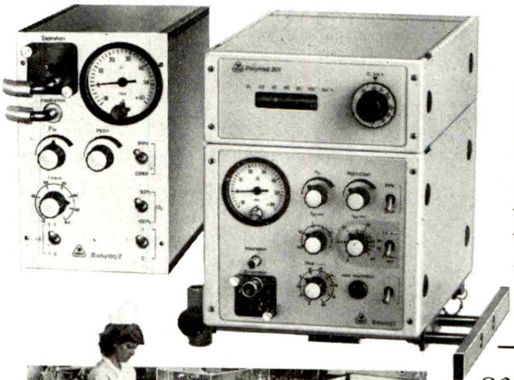
Look, no cut-backs!



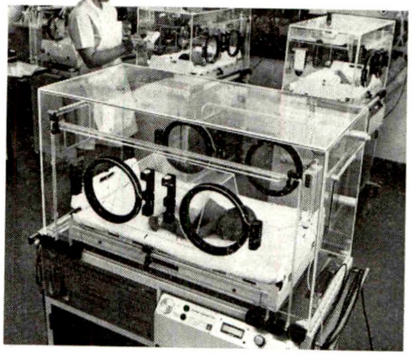
Use the new Draeger leasing plan and get the equipment you want now without touching your Capital Allocation.

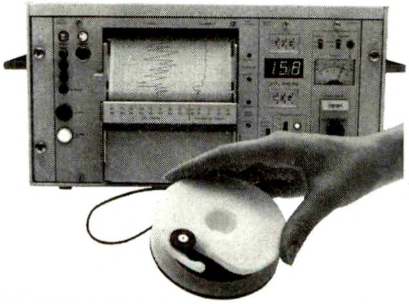
It's as if there haven't been any cut-backs or investment restraints.

Through the new Draeger leasing plan, you can go ahead and modernise without even going near your Capital Allocation funds.

Leasing payments are counted as running costs, not capital spending, so there is no drain on funds set aside for purchasing equipment.

If you've been waiting your turn in the budget queue, why not consider the waiting to be over?





Use the Draeger leasing plan to modernise now, with any of the following Draeger equipment:–

- –Incubators for the SCBU and transport.
- –Babytherm intensive care crib.
- –UV1 long-term ventilator for children and adults.
- –Babylog neonatal ventilators for the SCBU and transport.
- –Vapor 19 vaporisers for halothane and enflurane.
- –Washing, drying and disinfecting equipment.

Re-open your equipment shopping list now. Contact us for full details of the Draeger leasing plan.

CHARLES C THOMAS • PUBLISHER

MULTIPLE SCLEROSIS IN CHILDHOOD *by* **E. J. Field,** *Royal Victoria Infirmary, Newcastle Upon Tyne, England.* The author herein presents information on the diagnosis, treatment, and prevention of multiple sclerosis (MS). He demonstrates how a biochemical anomaly affecting unsaturated long chain fatty acids is involved in MS and is reflected in the surface membrane constitution of all body cells. He later shows how the familial pattern of MS can be identified at an early age and how his findings can be used to develop measures for preventing MS. *'79, 120 pp., 18 il. (3 in color), 17 tables, $12.75*

LIFE AND DEATH DECISIONS *edited by* **Arthur Winter,** *Hospital Center at Orange, Orange, New Jersey. (6 Contributors)* The contributors to this timely book grapple with the medical, legal, moral, and economic problems in decisions to begin or withhold, to continue or suspend extraordinary technological support of life. *'79, 96 pp., $10.50*

THE MALTREATED CHILD: The Maltreatment Syndrome in Children — A Medical, Legal and Social Guide (4th Ed.) *by* **Vincent J. Fontana,** *New York Foundling Hospital, New York, New York, and* **Douglas J. Besharov,** *U.S. National Center of Child Abuse and Neglect, Washington, D.C. Foreword by* **Mother Loretto Bernard.** New topics in this fourth edition include sexual abuse and sexual exploitation of children, abuse of adolescents, early treatment of the high-risk mother, prenatal intervention, and parent-infant bonding. *'79, 192 pp., 15 il., $14.50*

THE PHYSIOLOGY OF THE NEWBORN INFANT (4th Ed.) *edited by* **Clement A. Smith,** *Harvard Medical School, Boston, Massachusetts, and* **Nicholas M. Nelson,** *Hershey Medical Center, Hershey, Pennsylvania. (9 Contributors)* Much more than a mere treatment manual, this current review of neonatal and significant prenatal physiology provides the foundation for understanding the management of hyperbilirubinemia, the prevention of hyaline membrane disease, the approach to neonatal sepsis and many other important treatment procedures. *'76, 784 pp. (6 3/4 x 9 3/4), 260 il., 122 tables, $60.00*

LARYNGO-TRACHEAL PROBLEMS IN THE PEDIATRIC PATIENT *edited by* **Gerald B. Healy** *and* **Trevor J. I. McGill,** *both of Harvard Medical School, Boston, Massachusetts. (19 Contributors)* Pediatric otolaryngologists, pediatricians, and anesthesiologists combine their expertise to present this broad perspective of the problems of the pediatric airway. Topics include assessment of the child with stridor, acute inflammation of the larynx, and management of croup and epiglottitis. *'79, 128 pp., 31 il., 5 tables, $13.75*

THE X-RAY DIAGNOSIS OF CONGENITAL HEART DISEASE IN INFANTS, CHILDREN, AND ADULTS: Pathologic, Hemodynamic, and Clinical Correlations as Related to the Chest Film (2nd Ed.) *by* **Larry P. Elliott,** *Univ. of Alabama School of Medicine, Birmingham, Alabama, and* **Gerold L. Schiebler,** *Univ. of Florida College of Medicine, Gainesville, Florida.* For this new edition, chapters have been added on complex congenital heart disease and on analysis of cyanotic heart disease chest films. *'79, 448 pp. (6 3/4 x 9 3/4), 405 il., 13 tables, $36.50*

POISONING: Toxicology, Symptoms, Treatments (4th Ed.) *by* **Jay M. Arena,** *Duke Univ. Medical Center, Durham, North Carolina.* New material added to the Fourth Edition of this classic text concentrates on recent treatment controversies and new findings on environmental contaminants. The text continues to present authoritative data on the toxicology, symptoms, and treatments for poisoning from numerous toxic agents. *'79, 864 pp. (7 x 10), 39 il. (1 in color), 161 tables, $44.50*

CLEFT PALATE: MIDDLE EAR DISEASE AND HEARING LOSS *edited by* **Malcolm D. Graham,** *Univ. of Southern California School of Medicine, Los Angeles, California. Foreword by* **Brian F. McCabe.** *(10 Contributors)* The effect that cleft palate has on the speech, hearing, and education of the child is the focus herein. Otologic assessment and management are covered along with such clinical subjects as anatomy and pathology of cleft palate, pharyngeal disease and hearing loss, and abnormal tympanic membranes. *'78, 168 pp., 59 il. (25 in color), 4 tables, $16.50*

Review article

Current status of zinc in health and disease states

P. J. AGGETT AND J. T. HARRIES

Institute of Child Health, London

Even though brass, a zinc-copper alloy, had been known for centuries, metallic zinc was not isolated in Europe until 1509. The metal was then named zinken because of its superficial similarity to tin (German–zinn) (Wootton, 1910).

Zinc (atomic number 30; atomic weight 65·37) has a completed d subshell with 2 s electrons and the divalent cation is the only naturally occurring oxidation state. This relative stability, its ability to co-ordinate 4 or occasionally 6 ligands, and its capacity to act as a Lewis acid are probably fundamental to zinc's biological role. The biological importance of zinc was first discovered when Raulin (1869) demonstrated that it was necessary for the growth of *Aspergillus niger*. Subsequently, the ubiquitous distribution of zinc in nature was appreciated and the essentiality of zinc for higher plants (Mazé, 1914) and animals (Todd *et al.*, 1934) was established.

In man the medicinal use of calamine (zinc carbonate) is first recorded in *Papyrus Ebers* of 1550 BC (Ebers, 1937) but it was not until 1939 that it was suggested that zinc deficiency might contribute to the clinical manifestations of human vitamin deficiency syndromes such as beriberi (Eggleton, 1939). The first human zinc deficiency syndrome was identified in the early 1960s in malnourished adolescent boys in Iran and Egypt (Halsted *et al.*, 1972). A more profound deficiency state became apparent when Moyanhan and Barnes (1973) showed that treatment with zinc induced a complete and rapid clinical remission in a patient with acrodermatitis enteropathica.

Dietary sources and requirements

Good dietary sources of zinc (Underwood, 1977) are meat (20–60 μg (0·3–0·9 μmol)/g wet weight, and fish (15 μg (0·2 μmol)/g wet weight). Although cereals and vegetables have similar zinc contents (15–60 μg/g wet weight) to meats, the bioavailability of zinc from plant sources is reduced by their high phytate (inositol hexaphosphate) content which complexes the metal and prevents its absorption (Becker and Hoekstra, 1971). Diets containing phytate and zinc with a molar ratio in excess of 25:1 induce growth retardation in young rats (Davies and Oppin, 1979). Momcilovic *et al.* (1976) showed that the availability of zinc from a soya-based infant feed may be reduced by 20%. Complexation also occurs with fibre, hemicellulose, and clay; cellulose bulking agents reduce the absorption of the radioisotope ^{65}Zn (Becker and Hoekstra, 1971). Both calcium and phosphate reduce the utilisation of dietary zinc. Chelating agents such as EDTA, and animal protein may improve zinc availability from plant materials (Becker and Hoekstra, 1971), and its content in and availability from foodstuffs may be altered during food preparation (Halsted *et al.*, 1974).

The zinc content of cows' and human milk is variable (Picciano and Guthrie, 1976) and comparisons are unreliable. Human milk contains a low molecular weight zinc-binding ligand which probably facilitates absorption (see later); such a ligand is not present in cows' milk and zinc from this source to the human infant may be reduced (Eckhert *et al.*, 1977). A recent study on 6-month-old infants showed higher plasma zinc levels in those which were breast fed than in infants fed cows' milk-based formulae (Hambidge *et al.*, 1979). A longitudinal study has demonstrated that human breast milk zinc concentrations decrease with the duration of lactation (Vuori and Kuitunen, 1979). These are facts that need to be considered when evaluating the zinc nutritional value of infant feeds and of mature breast milk, especially when it is given to preterm infants in whom absorptive mechanisms may be immature (see later).

An adult consumes 10–15 mg (Underwood, 1977) of dietary zinc a day and the following age- and sex-related daily dietary allowances have been recommended by the National Research Council

---

Centre for Study of Metabolism of Trace Elements, University of Aberdeen
P. J. AGGETT, co-ordinator
Institute of Child Health, London
J. T. HARRIES, reader in paediatrics

Food and Nutrition Board (1974): 0–6 months, 3 mg (46 μmol); 6–12 months, 5 mg (76 μmol); 1–10 years, 10 mg (152 μmol); adolescent children, adult men, and nonpregnant women, 15 mg (230 μmol); pregnant women, 20 mg (305 μmol), and lactating mothers 25 mg (382 μmol). A WHO Expert Committee (World Health Organisation, 1973) prepared recommendations based on the bioavailability of dietary zinc but all such recommendations can only serve as tentative guidelines. In healthy children in the UK, Alexander *et al.* (1974) demonstrated an average daily intake of 0·3 mg (4·6 μmol)/kg; about 20% of which was absorbed.

Absorption

Zinc absorption occurs throughout the small intestine but most rapidly in the duodenum and proximal jejunum (Methfessel and Spencer, 1973), and is probably a carrier-mediated process (Davies, 1974). *In vitro* uptake studies in human small intestinal mucosa suggest that it is also an active energy-dependent process (Atherton *et al.*, 1979) and isopycnic ultracentrifugation studies (unpublished) on isolated enterocytes from this material indicate that the absorbed zinc is almost totally distributed in the cytosol fraction. ^{65}Zn can be detected in plasma 15 minutes after ingestion and reaches a peak 4 hours later (Spencer *et al.*, 1966); patients with an ileojejunal bypass appear to have reduced zinc absorption (Andersson *et al.*, 1976).

Low molecular weight (8000–10 000) zinc-binding ligands (ZBL) have been reported in the small intestine and pancreas of rats, in the pancreatic secretions of dogs (Evans, 1976a), and in rat and human milk (Hurley *et al.*, 1978). Although the precise functions of these ZBL have not been defined, they almost certainly facilitate zinc absorption from the intestinal lumen. The mucosal ZBL is absent in the newborn rat which is dependent on the maternal milk ZBL for optimum zinc absorption. This dependence is lost after 18 days, by which time the mucosal ZBL has developed and the exogenous ZBL no longer enhances zinc absorption (Duncan and Hurley, 1978). A similar process may operate in the human since some term and low birthweight preterm infants have an impaired capacity to absorb zinc (Cavell and Widdowson, 1964; Dauncey *et al.*, 1977) and the human breast milk ZBL content is highest in colostrum and diminishes thereafter (Hurley *et al.*, 1978).

A low molecular weight cytoplasmic zinc-metalloprotein designated zinc-metallothionein (Zn-MTN) because of its high cysteine content, has been identified in the liver and small intestinal mucosa (Cherian and Goyer, 1978), and its synthesis can be induced by parenteral or oral administration of zinc (Richards and Cousins, 1975). Its precise function is undefined but it may participate in the homeostatic regulation of zinc metabolism and absorption, and provide a source of zinc at times of deprivation. The relationship between ZBL and intestinal Zn-MTN has not been clarified. Zn-MTN may regulate zinc absorption by sequestering zinc within the enterocyte. This possibility is supported by the observation that there is an inverse relationship between intestinal zinc uptake and intestinal MTN content (Richards and Cousins, 1976). It has been suggested that zinc is taken up from the enterocyte basolateral membrane by transferrin and conveyed to the liver via the portal vein (Evans, 1976a, b). The mechanism of cellular uptake of zinc and its incorporation into metalloproteins has not been elucidated but the latter probably occurs after the synthesis of the apoprotein.

Excretion

The main excretory route for zinc is in the faeces (Underwood, 1977). Biliary losses are small but pancreatic secretion may contribute 25% of endogenous zinc loss (Stake *et al.*, 1974). The relative contributions to the remaining faecal loss by desquamation of surface epithelial cells or intestinal secretion has not been defined.

Renal conservation of zinc results in a daily urinary loss <600 μg (<9·2 μmol) (Underwood, 1977). The zinc concentration in neonatal urine may be 5 times that of adults (Cavell and Widdowson, 1964).

Sweat zinc loss is negligible in preadolescent children studied in temperate areas (Harrison *et al.*, 1975), but in tropical climates it may be significant. Secretion by this route is reduced with acclimatisation and in zinc deficiency states (Prasad *et al.*, 1963).

Body zinc distribution and mobilisation

A 70-kg man contains 1·4–2·3 g (21–35 mmol) of zinc (Widdowson *et al.*, 1951) and a term neonate has about 60 mg (0·9 mmol) (Widdowson and Spray, 1951). In the adult, this amount is about 40% of the total body content of iron and 10–20 times that of copper; there is relatively less zinc in the neonate and the corresponding ratios are 20% and 5 times respectively. Next to potassium, calcium, and magnesium, zinc is the most abundant intracellular metal and is located principally in the supernatant, microsomal, and nuclear fractions (Thiers and Vallee, 1957). Highest tissue concentrations (>500 μg (>7·7 μmol)/g dry weight) are found in the uveal tract, and postpubertal prostate gland and seminal fluid. Hair, nails, skin, and bones have a zinc content of 90–250 μg (1·4–3·8 μmol)/g, and the pancreas, liver, kidney, and muscle contain 140–230 μg (2·1–3·5 μmol)/g (Halsted *et al.*, 1974). Muscles in newborn animals have a similar zinc content but active muscle groups soon develop higher concentrations than less active groups (Cassens *et al.*, 1967).

Studies using ^{65}Zn show poor exchange of zinc deposited in bone, skin, and muscle and poor zinc mobilisation from these sources in rats at times of increased requirements, such as pregnancy (Hurley and Swennerton, 1971), suggest that these tissues which collectively contain 70–80% of the total body content of zinc do not provide an effective storage depot. In the young growing animal, however, release of bone zinc during the remodelling process may provide a reserve source (Brown *et al.*, 1978). The fetal zinc content increases in proportion to body weight and there is little evidence of intrauterine storage of the element; however the possibility that hepatic zinc in the neonate may provide an additional store remains to be elucidated.

Erythrocyte zinc (10–14 μg/g) (Halsted *et al.*, 1974) is predominantly located in the enzyme carbonic anhydrase and comprises 75–88% of the whole blood zinc content, the remainder being principally in the leucocytes (3%) and plasma (12–20%) (Vallee and Gibson, 1948); individual leucocytes contain about 25 times as much zinc as erythrocytes. Most of the plasma zinc is bound to albumin (50%) and an α_2-macroglobulin (30–40%), a small amount is associated with a β-globulin (transferrin) and with free amino-acids (2–8%) (Prasad and Oberleas, 1970).

Analytical values of plasma zinc vary slightly with the technique used for their assay but most laboratories providing such a service have determined their own normal range. The paediatric range established at The Hospital for Sick Children, London (Aggett *et al.*, in preparation) is 11–24 μmol/l (72–157 μg/100 ml).

Plasma zinc levels fall within hours of stress—such as surgery, trauma, or inflammation—and remain low with chronic stress. This is caused by a protein, leucocyte endogenous mediator (LEM), which is released from activated phagocytes and which enhances hepatic uptake of zinc and iron as well as synthesis of acute phase proteins including caeruloplasmin (Beisel *et al.*, 1976). Zinc is redistributed among its plasma ligands, and increased binding to low molecular weight ligands such as amino-acids may underlie the zincuria which can accompany stress. It is unclear at present whether LEM is a number of similar proteins or a single multifunctional entity. Plasma zinc levels are also frequently depressed in patients with neoplasia.

Assessment of zinc status

There is no reliable means currently available for determining the body zinc status in routine clinical practice. Plasma zinc levels are subject to acute variations and a single low value should be interpreted cautiously in conjunction with other factors, such as the patient's clinical condition. Serum levels are 16% higher than plasma levels partly as a result of the release of zinc from platelets and unavoidable haemolysis (Foley *et al.*, 1968). Hair zinc levels correlate poorly with plasma levels but provide historical information which is of value in epidemiological studies. Low hair zinc levels in one study were associated with zinc-responsive symptoms (Hambidge *et al.*, 1972) and probably represented previous zinc nutritional status. The interesting report of Heinersdorff and Taylor (page 958) showing a lower hair zinc content in boys aged 10–11 compared with similarly aged girls may reflect other, possibly physiological, influences which merit further investigation. Erythrocyte or leucocyte zinc determinations may prove to be more reliable then plasma levels, but the fact that the erythrocyte zinc content rises progressively during the first 12 years of life (Berfenstam, 1952) limits its application in children. Determination of urinary zinc is also unreliable, but it has been suggested that the urinary sulphate content could be of some value (Hsu and Anthony, 1971). In some studies salivary zinc has been measured (Henkin *et al.*, 1975a). Tissue analysis, ^{65}Zn turnover, and balance studies are essentially research tools. It should be stressed that all specimens for zinc determination must be collected with great care and stored in zinc-free containers to avoid haemolysis and contamination. Reduced activity of zinc-dependent enzymes, such as alkaline phosphatase, often accompanies a reduction in plasma zinc in deficiency states, and may provide a valuable clue particularly when facilities for determining zinc are not readily available. At present, the best criterion of zinc deficiency is an unequivocal clinical response to zinc administration.

Biological functions

Enzyme activities. Zinc is essential for the activity of at least 90 enzymes which participate in all the major metabolic pathways. Over 40 metalloenzymes exist in which zinc is bound tightly to the apoenzyme in specific stoichiometric ratios and in which it serves one or more structural, regulatory, or catalytic functions (Riordan and Vallee, 1976). Mammalian metalloenzymes include carbonic anhydrase, carboxypeptidases, aminopeptidases, alkaline phosphatase, alcohol, retinol, malate, lactate, glutamate, and glyceraldehyde-3-phosphate dehydrogenases. Some metalloenzymes require additional metals for activity, cytosolic superoxide dismutase, for example, has a requirement for copper as well as for zinc.

Other metalloenzymes have only been identified in lower species and the particular metal dependence of an enzyme varies between species. Both DNA and RNA polymerases are zinc metalloenzymes in *Escherichia coli*; it has not been established that these are metalloenzymes in mammals but studies on animals indicate that thymidine kinase activity and nucleic acid synthesis are zinc-dependent in mammals. In some oncogenic viruses the reverse transcriptase (that is, RNA-dependent DNA polymerase) is a zinc metalloenzyme (Vallee, 1977). There is evidence that zinc is important for optimal activity of aspartate transcarbamylase, δaminolaevulinic acid dehydratase activities (Riordan and Vallee, 1976), ornithine transcarbamylase (Rabbani and Prasad, 1978), and in fatty acid metabolism (Hambidge *et al.*, 1978).

Zinc-deficient animals have impaired collagen synthesis and poor wound healing. This may reflect a generalised defect in protein and nucleic acid synthesis; however some evidence suggests that zinc deficiency alters the quantity and type of collagen cross links (Fernandez-Madrid *et al.*, 1976).

Cell function. Zinc is essential for all phases of the cell cycle, but, as yet, there is little evidence to relate this directly to its effects on nucleic acid and protein synthesis. Deficiency is associated with RNA disaggregation and increased ribonuclease activity (Prasad and Oberleas, 1973), and the ability of zinc to inhibit adenylate cyclase and phosphodiesterase may indicate a role in cell function and genetic expression by regulating the relative intracellular concentrations of cyclic-AMP and cyclic-GMP (McMahon, 1974). Cell replication rates in the oesophagus and pancreas of zinc-deficient rats are increased (Fell *et al.*, 1973), suggesting that a loss of genetic regulation precedes an effect on nucleic acid and protein synthesis. In human lymphocytes zinc acts as a mitogen, but here again the mechanism is unclear but appears to be mediated by monocytes (Rühl and Kirchner, 1978). Zinc stabilises plasma and subcellular membranes (Chvapil, 1976) as well as nucleic acids and microtubules (Nickolson and Veldstra, 1972); it stabilises lysosomes and high concentrations *in vitro* inhibit leucocyte mobility and phagocytosis while enhanced macrophage migration has been described in zinc-deficient guinea-pigs (Chvapil, 1976); membrane lipid peroxidation is increased in zinc deficiency states, and it has been proposed that zinc protects membranes from free radical oxidation (*Lancet*, 1978).

Endocrine function. Insulin is stored in the β-cells of the pancreas as a hexamer with 2 atoms of zinc (Adams *et al.*, 1969), and zinc appears to influence insulin binding and degradation at the hepatocyte plasma membrane (Arquilla *et al.*, 1978). In some studies impaired glucose tolerance and insulin response have been associated with zinc deficiency, but this has not been a consistent feature (Kirchgessner *et al.*, 1976).

Prostatic androgen metabolism is modified by the intracellular concentration of zinc, and both high and low tissue concentrations inhibit the transformation of testosterone to dihydrotestosterone (DHT) (Habib, 1978). Hartoma *et al.* (1977) demonstrated improved sperm counts and testosterone levels in hypozincaemic oligospermic males as a result of zinc administration; this treatment has also reversed uraemic impotence and increased DHT levels in patients with renal dialysis (Antoniou *et al.*, 1977).

Taste. It has been suggested that zinc may play a physiological role in taste (Henkin *et al.*, 1975a, b) and in this context is it of interest that 2 similar zinc metallo-proteins, gustin and nerve growth factor, have been isolated from human and murine saliva respectively and appear to combine with their respective taste buds and to be essential for their normal morphology and optimum function (Henkin, 1978).

Zinc deficiency states

Zinc deficiency can result from an inadequate dietary intake, malabsorption, increased body losses, intravenous feeding, or a combination of

Table 1 *Causes of zinc deficiency*

- Inadequate dietary intake
  - Protein-calorie deficiency
  - Vegetarianism
  - Patients on protein-restricted diets
  - Synthetic diets
- Malabsorption
  - Acrodermatitis enteropathica
  - Coeliac disease and other enteropathies
  - Pancreatic insufficiency
  - Chronic inflammatory bowel disease
  - Immaturity of absorptive systems
- Increased body losses
  - Starvation
  - Burns
  - Diabetes mellitus
  - Ketoacidosis
  - Diuretic treatment
  - Proteinuria
  - Hepatic disease
  - Intravascular haemolysis (for example, sickle cell anaemia)
  - Porphyria
  - Chelating agent therapy
  - Chronic blood loss
  - Parasitic infection
  - Dialysis
  - Exfoliative dermatitis
  - Excessive sweating
- Intravenous feeding

several of these predisposing factors. Some examples are listed in Table 1; in some instances there is no conclusive evidence of zinc deficiency (see above) but all constitute 'at risk states' and have been associated with markedly reduced plasma or serum zinc levels, some of which deserve comment.

Inadequate dietary intake. Protein-calorie malnutrition in the developing parts of the world is probably the most common cause of zinc deficiency, but Western populations may be at risk from a marginal zinc intake. This may be the case in vegans, vegetarians (Bodzy *et al.*, 1977), low socioeconomic groups subsisting on low meat diets (Hambidge *et al.*, 1972, 1976), and patients with chronic renal disease on low protein diets (Rose and Willden, 1972). Synthetic diets used in the treatment of children with inborn errors of metabolism and dietary intolerances require zinc supplements (Alexander *et al.*, 1974; Thorn *et al.*, 1978), and this may be the case for soya-based infant formulae although it has not yet been assessed. It is conceivable that the ingestion of texturised vegetable protein meat extenders and other novel protein sources, or calorie-controlled diets may be at risk. The need for fuller evaluation of feeding practices is stressed by the work of Walravens and Hambidge (1976) who demonstrated an improved growth rate in baby boys receiving standard formulae containing zinc supplements.

Malabsorption. Defective absorption of zinc may be secondary to the immaturity of its absorption systems, as may be the case in newborn babies especially if preterm (Dauncey *et al.*, 1977). Any individual with gastrointestinal disease is potentially at risk of developing zinc deficiency, particularly if the condition is long standing. Deficiency may result from intraluminal binding of zinc to high affinity ligands, impaired secretion of pancreatic ZBL, defective uptake into mucosa, reduced mucosal ZBL, or increased secretion into the intestinal lumen. The pathophysiological mechanisms which operate in the genesis of zinc deficiency in various disorders of the gastrointestinal tract present an important and challenging area for future research.

In 1973 Moynahan and Barnes made the important discovery that all the clinical manifestations of acrodermatitis enteropathica (AE) resolved strikingly with oral zinc treatment (Moynahan, 1974). This historic discovery undoubtedly added a major motivation and impetus to research concerned with zinc in health and disease states in man. Impaired ^{65}Zn absorption has been shown in AE (Lombeck *et al.*, 1975), and balance studies have shown that patients are in a net negative state with respect to zinc, and that this is accounted for by increased faecal losses (Aggett *et al.*, 1978). Although these observations suggest malabsorption of zinc, they do not define the pathogenesis of malabsorption. We have demonstrated a pronounced defect in the *in vitro* uptake of zinc in jejunal biopsies obtained from patients with AE, both when they are in remission and relapse (Atherton *et al.*, 1979). Thus the primary abnormality in AE may be defective zinc uptake into the enterocytes and the condition represents an addition to the known selective inborn errors of absorption (Harries, 1977). Recently preliminary evidence of defective zinc binding by duodenal juice of patients with AE has been reported (Casey *et al.*, 1978).

Increased body losses. Increased body losses may occur in a wide variety of conditions, as shown in Table 1.

Intravenous feeding. Intravenous feeding, particularly if prolonged, carries a risk of zinc deficiency. This is in part secondary to the variable but low content of zinc in the administered solutions (van Caillie *et al.*, 1978) and to the excessive urinary losses of zinc complexed with carbohydrates or amino-acids, or both (Freeman *et al.*, 1975). It is particularly likely to occur during an anabolic phase where there is an abrupt increase in body requirements and it is important to monitor zinc status during and after reintroduction of oral feeding (Fleming *et al.*, 1976).

Clinical manifestations of zinc deficiency

The variable and protean clinical manifestations of zinc deficiency are listed in Table 2. Anorexia, growth retardation, and impaired taste and olfactory sensation, are early features as is mood alteration. Most neurological features have been described in adults with induced zinc deficiency (Henkin *et al.*, 1975b); jitteriness and altered behaviour have been

Table 2 *Clinical manifestations of zinc deficiency*

Anorexia
Impaired taste and smell
Pica
Growth retardation
Hypogonadism
Impotence in renal dialysis patients
Depression, mood lability, impaired concentration
Intention tremor
Nystagmus
Dysarthria
Jitteriness
Photophobia, night blindness, blepharitis
Skin lesions (digits, perineum, parietal, nasolabial folds)
Paronychiae with monilial superinfection
Nails (growth arrest, loss, Beau's lines)
Hair growth arrest or alopecia
Delayed wound healing
Diarrhoea

reported in infants (Sivasubramanian and Henkin, 1978). Cutaneous signs range from a rough skin to a severe eczematous dermatitis affecting the digits, perineum, mouth, and nasolabial folds.

The biochemical consequences of zinc deficiency in human adults include reduced plasma alkaline phosphatase and lactate dehydrogenase activities, raised plasma ammonia, and increased plasma ribonuclease activity (Prasad *et al.*, 1978b).

Impaired night vision might be more associated with impaired retinol dehydrogenase activity (Huber and Gershoff, 1975) than with any specific effect zinc deficiency may have on retinol-binding protein synthesis (Carney *et al.*, 1976).

Impaired cell-mediated immunity with poor lymphoblast response, absent skin sensitivity reactions (Golden *et al.*, 1978), thymic hypoplasia (Golden *et al.*, 1977), and defective monocyte and polymorphonuclear leucocyte mobility have been associated with zinc deficiency and may contribute to the infections which occur particularly in patients with AE (Weston *et al.*, 1977).

In the pregnant rat even transient zinc deficiency results in an increased incidence of fetal resorption, stillbirths, and abnormalities of the CNS, skeleton, lung, urogenital tract, and palate in the offspring; moreover, the newborn rats tend to be of low birthweights with altered learning and behavioural patterns (Hurley and Mutch, 1973). The last features have also been described in rhesus monkeys (Sandstead *et al.*, 1978). The one abortion and the 2 congenital abnormalities reported in the 7 recorded pregnancies of 3 women with AE suggest that similar effects may apply to the pregnant human (Hambidge *et al.*, 1975). It has been speculated that the high incidence of anencephaly in some Middle Eastern countries may be the result of environmental zinc deficiency (Sever and Emanuel, 1973). Serum zinc levels in women having abnormal deliveries or low birthweight or preterm infants were lower than in women not experiencing such abnormalities (Jameson, 1976). A causal relationship was not established however.

Treatment of deficiency states

Zinc can be administered as a sulphate (22·5 mg (350 μmol) of elemental Zn/100 mg), acetate (30 mg (460 μmol) Zn/100 mg), or oxide (80 mg (1·2 mmol) Zn/100 mg) salts. Zinc gluconate preparations are also used. In some individuals the salt, particularly the sulphate, can be irritant to the gastrointestinal tract and in these circumstances the zinc salt may be taken with a meal or capsulated preparations may be better tolerated; but zinc is less efficiently absorbed with meals and from capsules (Oelshlegel and Brewer, 1977). These zinc salts have a wide therapeutic index and their doses should be adjusted according to the clinical response. In deficiency states an initial daily dose of 15 μmol elemental Zn/kg is given orally, or 5 μmol/kg IV. For maintenance IV therapy 2 μmol/kg is given daily at first. Larger oral doses are necessary in patients with AE. Plasma zinc and copper should be monitored frequently in these circumstances.

Zinc salts have also been used in the treatment of gastric ulcers (Frommer, 1975), rheumatoid arthritis (Simkin, 1976), and acne (Michaëlsson *et al.*, 1977). These applications await further evaluation and the consequences of prolonged oral zinc administration (see below) indicate that such use of zinc should be undertaken cautiously.

Toxicity

Zinc salts are usually well tolerated, but toxic effects have been associated with oral ingestion of elemental zinc (Murphy, 1970), zinc sulphate capsules (Moore, 1978), the use of water from galvanised containers for drinking (Brown *et al.*, 1964) and home dialysis (Gallery *et al.*, 1972), sucking zinc alloy toys (Chunn, 1973), prolonged oral zinc supplements (Prasad *et al.*, 1978a), and intravenous overdosage (Brocks *et al.*, 1977). Symptoms include anorexia, nausea, vomiting, lethargy, dizziness, diarrhoea, and bleeding gastric erosions; raised serum amylase and lipase were noted by Murphy (1970), and copper deficiency with hypochromic anaemia with reduced plasma copper concentrations have been reported after prolonged treatment with oral zinc. Intravenous overdosage has been associated with acute renal failure and death. Contact dermatitis to zinc salts (Freeman, 1942) and zinc allergy in diabetics on zinc insulin preparations have also been described (Feinglos and Jegasothy, 1979).

We thank the Medical Research Council and the Cystic Fibrosis Research Trust for financial support to investigate various aspects of trace metal metabolism in childhood, participation in this work having greatly facilitated the preparation of this paper.

Coronary arterial lesions and myocardial necrosis in stillbirths and infants

D. J. DE SA

Department of Pathology, McMaster University Medical Centre, Hamilton

SUMMARY In a detailed study of the coronary arterial tree and myocardium in 256 stillbirths and infants, abnormalities of the coronary arterial tree were noticed in 79 infants, and necrotic lesions of the myocardium in 111 infants. Of the 79 infants with arterial lesions, 70 had associated myocardial necrosis or scarring, or both; the group with coronary arterial lesions, therefore, accounted for the majority of cases with myocardial damage.

The myocardial lesions varied from small zones of subendocardial damage, to larger 'geographical' zones of necrosis scattered haphazardly through the myocardium, and a small group where massive necrotic lesions of the papillary muscles were present. While the coronary arterial lesions were associated with all three patterns, they were particularly found in association with the 'geographical' and papillary muscle changes.

The coronary arterial lesions varied from zones of acute focal, medial necrosis to severe proliferative intimal lesions and medial defects, with a distinct progression of changes from the acute to the more established lesions. The coronary arterial lesions were seen most commonly in association with conditions that could produce severe hypoxia, and it is argued that they result from hypoxia. It is suggested further that the myocardial damage, so commonly associated with the coronary arterial lesions, could compromise the ability of the hypoxic infant to respond to such an insult.

The coronary arterial lesions seen in this group of young infants could offer one explanation for the later development of a variety of other pathological conditions seen in adolescents and young adults.

In 1946 Dock described proliferative intimal changes in the coronary arterial tree of infants and young adults, and his findings were confirmed and extended by many others (Fangman and Hellwig, 1947; Minkowski, 1947; Lober, 1953; Levene, 1956; Schornagel, 1956; Moon, 1957; Robertson, 1960; Vlodaver *et al.*, 1967). Gruenwald (1949) reported necrotic lesions in the coronary arteries of 21 stillbirths and infants and he commented on their association with small foci of myocardial necrosis. He was unable, however, to follow their natural history.

Several reports describe myocardial necrosis in newborn babies and infants. Esterly and Oppenheimer (1967), and Franciosi and Blanc (1968) found evidence of myocardial necrosis in infants with a variety of congenital malformations of the heart and great vessels. Berry (1967), in a review of cases of myocardial necrosis occurring in infants and young children, reported several infants with myocardial necrosis, one of whom showed evidence of coronary artery occlusion. Gault and Usher (1960) described a neonate with coronary thrombosis and myocardial infarction complicating birth asphyxia. Bucciarelli *et al.* (1977), in a study of acquired tricuspid insufficiency in the newborn, found large areas of necrosis in the anterior papillary muscle of one such infant, but did not mention any changes in the coronary vessels.

In an earlier paper (de Sa, 1977), a wide spectrum of myocardial lesions was found in a group of immature hypoxic infants whose lives had been sustained by prolonged assisted ventilation. In that report, destructive lesions of the smaller, intramural branches of the coronary arterial tree were noted but were not elaborated on. The present report is

D. J. DE SA, associate professor of pathology

based on a detailed study of the coronary arterial tree in 256 stillbirths and infants. The presence of non-flammatory, necrotic, and degenerative lesions of the coronary arterial tree is described and their close association with myocardial necrosis and scarring is stressed.

Materials and methods

The necropsy records of the McMaster University Medical Centre provided most of the case material, but additional material was obtained through the co-operation of colleagues in St Joseph's and Henderson General Hospitals and the forensic pathology unit, Hamilton. The hearts and coronary vessels of 82 fresh stillbirths, 86 first-week neonatal deaths, 33 other neonatal deaths ages <28 days, 24 infants requiring prolonged ventilation (de Sa, 1977), 13 cases of sudden infant death syndrome, and 18 other infants age <one year were studied. In most instances the necropsies were conducted personally or the heart was available for a detailed study. Apart from the blocks of myocardium selected for routine histology, samples of myocardium were available in the reserve stocks taken at the time of necropsy. Even in retrospect, therefore, a detailed examination could be made.

Hearts with congenital malformations of the septum, great vessels, or valves were excluded. Multiple blocks of myocardium, including endocardial and epicardial surfaces, were embedded in paraffin and each block was studied at several different levels.

The numbers of blocks studied depended on the size of the heart. However, in all cases, at least 3 blocks were taken through the free wall of both ventricles, and these included the papillary muscles and atrioventricular grooves. In addition, at least 3 blocks were sampled through the entire thickness of the interventricular septum, including both anterior and posterior epicardial surfaces. Separate blocks were taken to include the left and right coronary arteries near their respective aortic ostia. In the larger hearts, further transversely orientated blocks were taken through an area of myocardium bounded posteriorly by the opening of the coronary sinus and extending anteriorly to include membranous interventricular septum and adjacent muscularis for a distance of approximately 0·3 cm. These blocks included the atrioventricular node, bundle of His, and both bundle branches. Sections were cut through these blocks at several levels and stained with a variety of standard histological techniques, as appropriate.

In some cases, blocks of formalin-fixed tissue were processed for ultrastructural study after selecting the areas under a Leitz dissecting microscope. These blocks were embedded in epon, and sections were cut at 1μm and stained with toluidine blue. Specific areas were chosen from these blocks and sectioned on an LKB ultramicrotome and stained with lead citrate and uranyl acetate, and examined on a Philips 300 electron microscope.

Results

Myocardial lesions. In this series, myocardial lesions (including acute necrosis, replacement with granulation tissue and/or scarring) were found in 111, and coronary arterial lesions (to be described below) were found in 79 (31 %) of the 256 infants. However of the 79 infants with coronary arterial lesions, 70 (89 %) had associated myocardial lesions. Infants with coronary arterial lesions, while only constituting a minority of the infants studied, accounted for most cases (70 of 111 or 63 %), with histologically detectable myocardial damage.

The myocardial lesions that were identified were similar in their range and severity to those identified as part of the considerably smaller, earlier series (de Sa, 1977). Generally focal band-like areas of necrosis or scarring were present (83 of 111 infants). These lesions were most often seen in the subendocardial areas of the myocardium (Fig. 1) but not exclusively so. Next in frequency (29 of 111 infants) were irregular geographical areas of necrosis or scarring, scattered haphazardly through both ventricles often associated with small collars of surviving myocardium around intramural vessels (Fig. 2). Finally large areas of necrosis or scarring affecting appreciable areas of papillary muscles were identified in 16 of the 111 infants (Fig. 3). As Table 1 shows, several infants had more than one pattern of necrosis. Furthermore, it is clear that while coronary arterial damage was associated with all three patterns of injury, it was more often associated with the larger lesions.

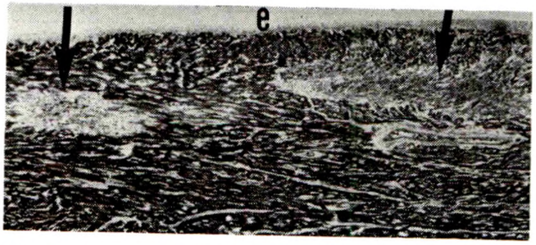

Fig. 1 *Small zones of subendocardial fibre necrosis (arrows) are seen in the heart of this 14-day-old infant, 34 weeks' gestation. Lesion on left is somewhat more advanced. Endocardial surface is indicated by 'e'. Gomon's trichrome (GT) × 150.*

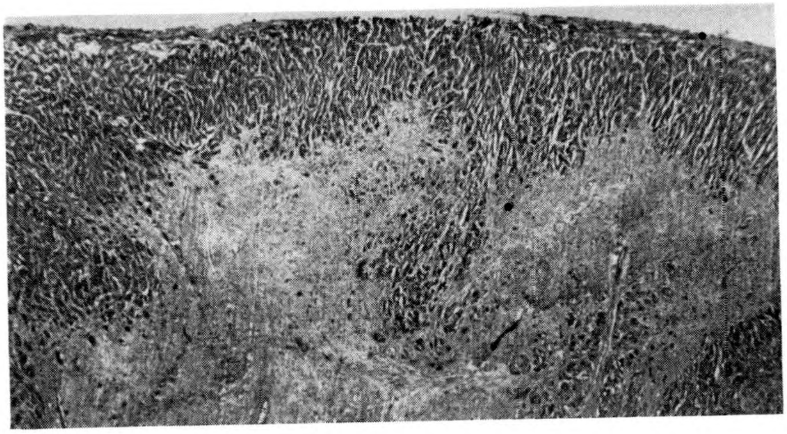

Fig. 2 *Large, pale-staining 'geographical' zones of scar tissue, replacing areas of previous myocardial necrosis are seen in this section through the interventricular septum of a 102-day-old infant, maintained on prolonged ventilation. GT* × 25.

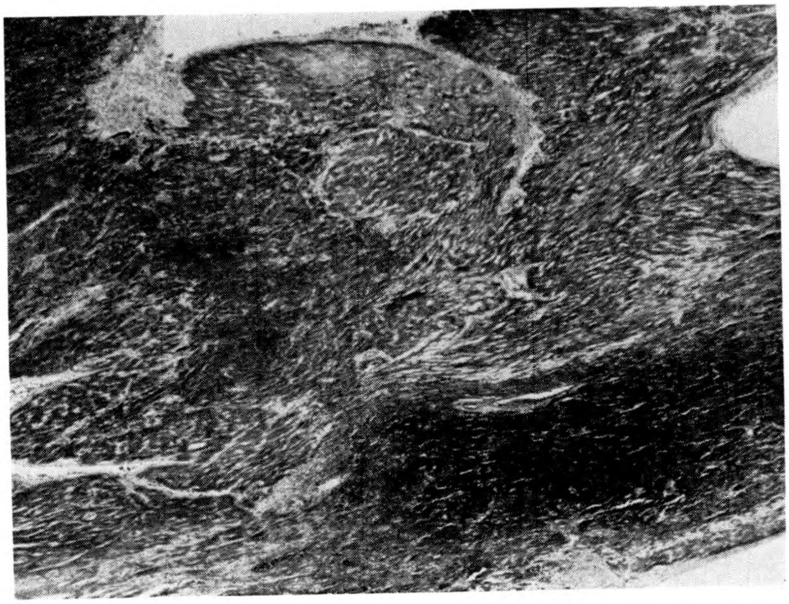

Fig. 3 *Section shows massive acute necrosis (darkly stained) occurring in the posterior papillary muscle of the mitral valve of a 5-day-old infant, 29 weeks' gestation, born after a pregnancy complicated by abruptio placentae. GT* × 180.

Histological findings in the coronary vessels

The impetus for the present study was provided by a chance observation of a section through an epicardial petechial haemorrhage in a one-day-old infant of 28 weeks' gestation, which showed an area of obvious medial necrosis in the anterior descending coronary artery. In adjacent sections disruption of the internal elastic lamina, early thrombus formation, and imminent rupture of the wall were demonstrated (Fig. 4).

Early necrotic lesions appeared as small areas of smudging of medial cellular detail. They were seen to greatest advantage near areas of perivascular petechial haemorrhages, associated with the rupture of small capillaries in connective tissue around the larger vessels, both on the surface of the heart and intramurally. The lesions were readily seen in 1 μm sections (Fig. 5). In many of these cases, step sectioning through the block showed focal micro-

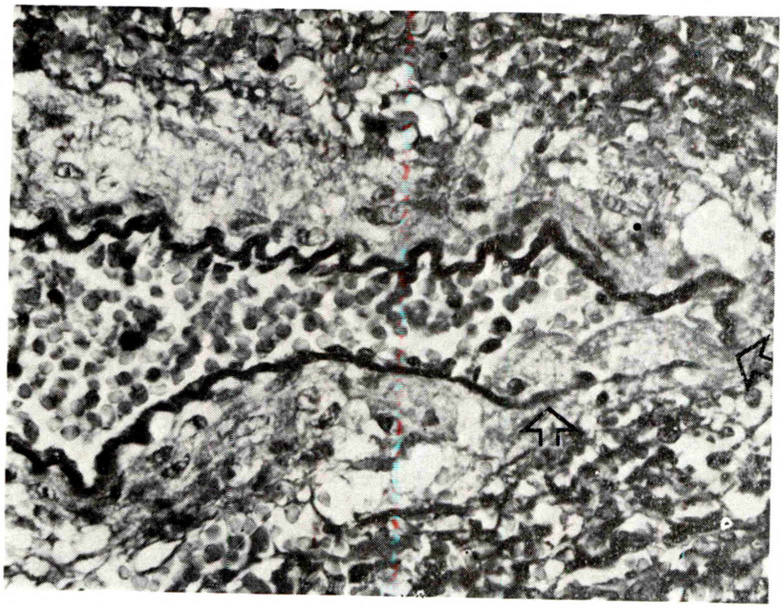

Fig. 4 *Disruption of the internal elastic lamina (zone between arrows), is seen in this section, through the anterior descending coronary artery of a 2-day-old infant of 28 weeks' gestation. Note globular, amorphous masses of thrombus present in relation to area of destruction of the internal elastic lamina. Haematoxylin, alcian green, elastic, Van Gieson (HAEVG)* × 1000.

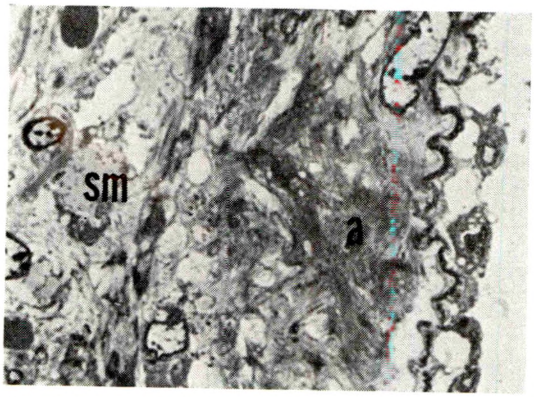

Fig. 5 *Plastic-embedded section through an area of very early medial necrosis in an infant of 31 weeks' gestation, 2 days' postnatal age. Media show an acellular area 'a' where the smooth muscle cells are destroyed and replaced by an amorphous fibrillary mass. Note also vacuolated smooth muscle cells 'sm' scattered through the wall. Toluidine blue (TB) × 2200.*

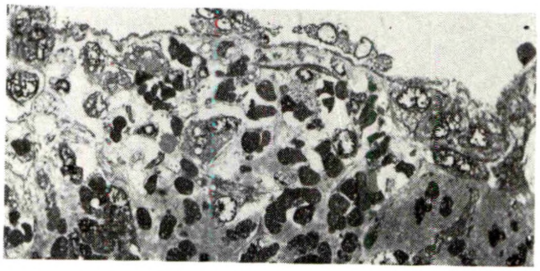

Fig. 6 *Plastic-embedded section from the same vessel as in Fig. 5. Luminal surface is in upper segment of figure and several areas of denudation of the intimal cells are present. Striking feature however is presence of large numbers of darkly-stained red cells present within wall of the artery. These red cells dissect between and separate small groups of smooth muscle cells. In this section no break in the internal elastic lamina was noted. TB × 1200.*

dissection (Fig. 6) with infiltration of red cells through and among degenerate muscle cells of the media. The extent of muscle necrosis in affected vessels varied considerably, from large geographical defects in the media to exquisitely selective focal loss of muscle cells (Figs 7 and 8). A striking feature was the absence of any significant inflammatory reaction and the necrotic lesions were not due to a primary arteritis.

Accompanying the loss of muscle cells in the media, there was aneurysmal dilatation and microdissection resulting in the formation of false aneurysms. In one infant it was possible to trace the development of a false aneurysm (Fig. 9) through the stages of muscle necrosis, microdissection, and enlargement until it eventually disappeared.

Small, nonocclusive thrombi were quite commonly present in the lumina of damaged vessels (Fig. 10). In these infants the small peripheral vessels within the myocardium contained small thromboemboli

(Fig. 11), and, occasionally, early organisation of embolus and its incorporation below the endothelium of small vessels could be identified.

The spectrum of changes described in the preceding paragraphs were more commonly seen in the stillbirths and younger infants in the series, and were found more readily in hearts with endocardial and epicardial petechial haemorrhages. The affected vessels varied in size and the largest ones, in this particular series, were the first major branches of both right and left coronary arteries (anterior descending branch of left coronary artery, lateral branch of right coronary artery). In this series acute necrotic lesions of the main right and left coronary arteries were not identified.

The older infants in the series showed a somewhat different spectrum of changes. The least obvious lesions consisted of small scars of media, with

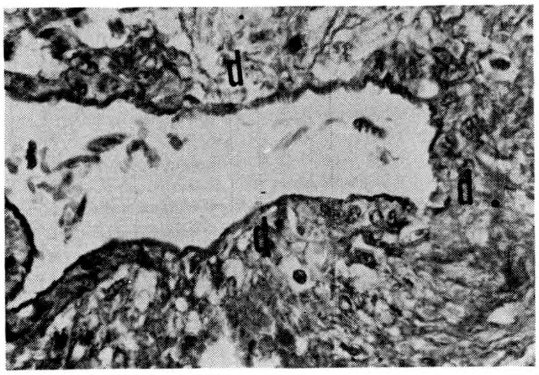

Fig. 7 *Section through a branch of the circumflex artery, 35 weeks' gestation, 3-day-old infant, showing large defects 'd' in the media. Note absence of any inflammatory reaction. HAEVG, × 700.*

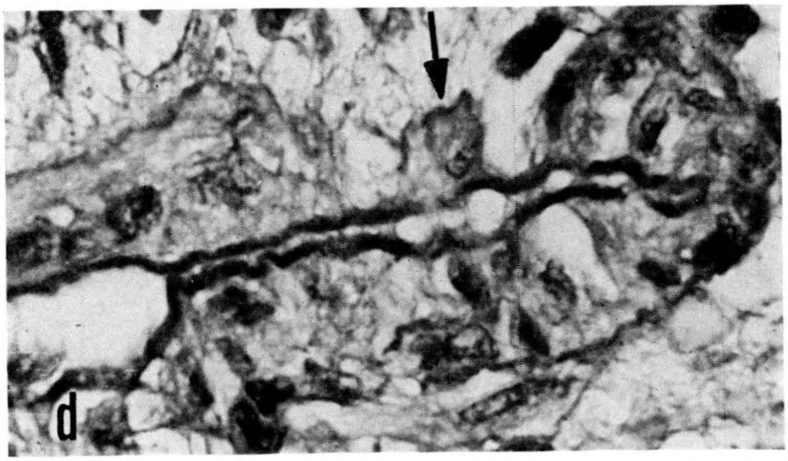

Fig. 8 *Same case as Fig. 7 taken from a lateral branch of the anterior descending coronary artery, showing single surviving smooth muscle cell of the media (arrow) and also a larger defect 'd' in the medial musculature. HAEVG, × 1600.*

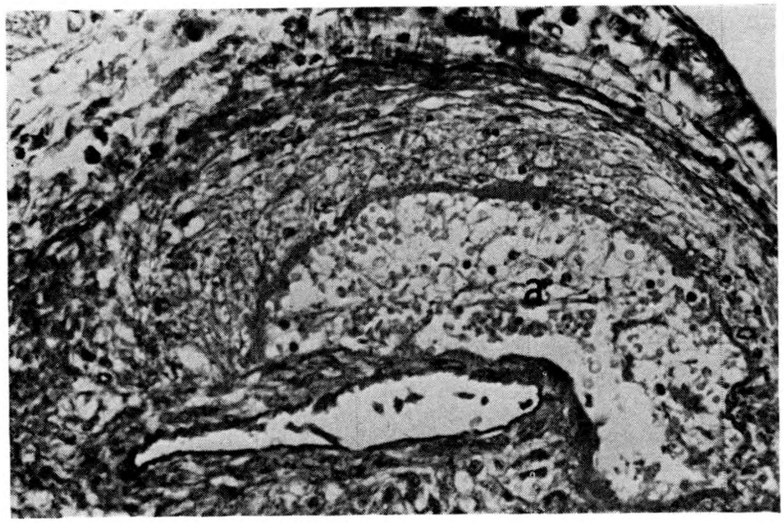

Fig. 9 *Posterior interventricular branch of the right coronary artery in a 39-week-gestation infant aged 9 days. A large false aneurysm of the wall 'a' is shown. In serial sections its development from areas of microdissection could be traced. HAEVG, × 450.*

excessive accumulation of acid mucopolysaccharide and fragmentation of the elastica (Fig. 12). In many of the older infants different stages in the organisation of thromboemboli within peripheral branches were present, amounting in some instances to obliteration of the lumen (Fig. 13). There was also evidence of progressive recanalisation of the vessel lumen (Fig. 14) and the affected vessels showed very obvious distortion of their architecture (Fig. 15). Many severely damaged vessels, with cellular intimal plaques overlying areas of pronounced medial hypoplasia were present (Fig. 16).

In many of the older infants prominent intimal

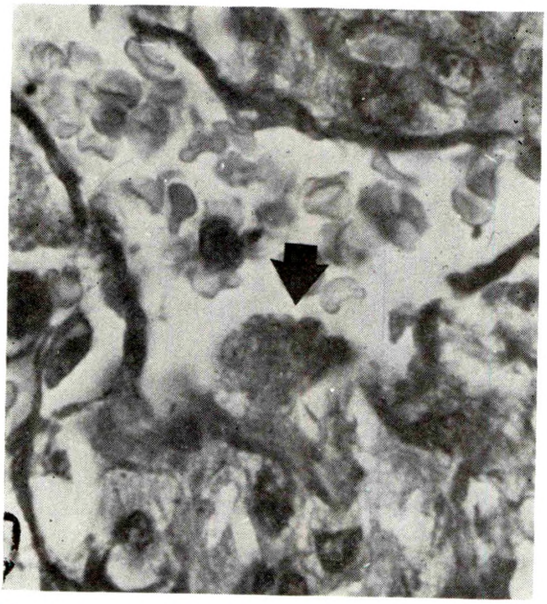

Fig. 10 *Serial section from same vessel as Fig. 6, showing a small mushroom-like thrombus protruding into the vascular lumen (arrow). HAEVG,* × *4000.*

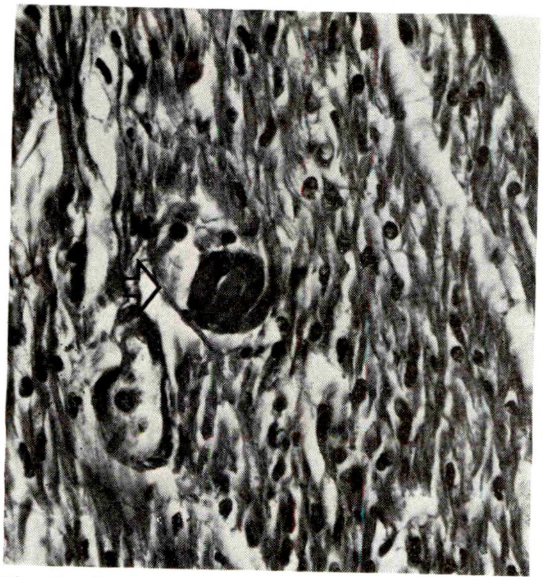

Fig. 11 *Intramural thromboembolus (arrow) in 35-week-gestation infant aged 5 days. Embolus is attached to the vessel wall and in other serial sections an early stage of endothelialisation was evident. Martius scarlet blue (MSB)* × *1000.*

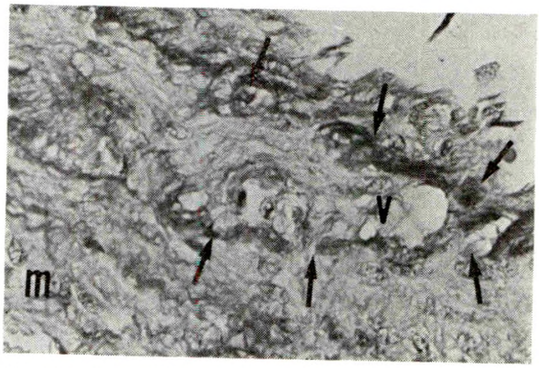

Fig. 12 *Circumflex artery in an infant of 26 weeks' gestation, 42 days' postnatal age. There is obvious splitting and reduplication of the internal elastic lamina (arrows). Large vacuoles 'v' staining faintly with alcian green, indicate presence of abnormal amounts of acid mucopolysaccharides. Note also the defects in the medial elastic tissue 'm'. HAEVG,* × *700.*

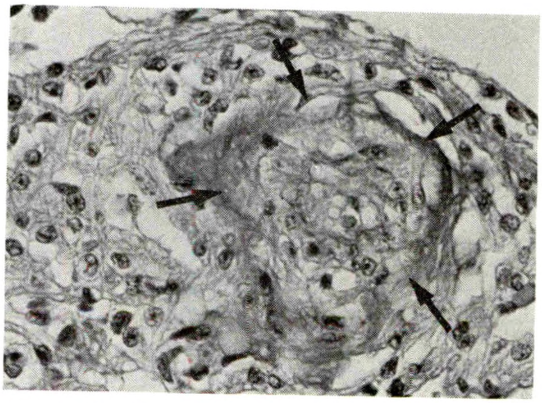

Fig. 13 *Section through base of the anterior papillary muscle of the mitral valve in a 3-month-old infant, born at 29 weeks' gestation, who presented as a 'sudden infant death'. An obliterated intramural vessel is outlined by arrows. Serial sectioning traced its origin from an intramural artery shown in Fig. 14. HAEVG,* × *1000.*

proliferation was noted in the surface vessels. There was disruption of the internal elastic lamina, irregular smooth muscle proliferation, and excessive deposits of collagen and elastic tissue in the intima (Fig. 17).

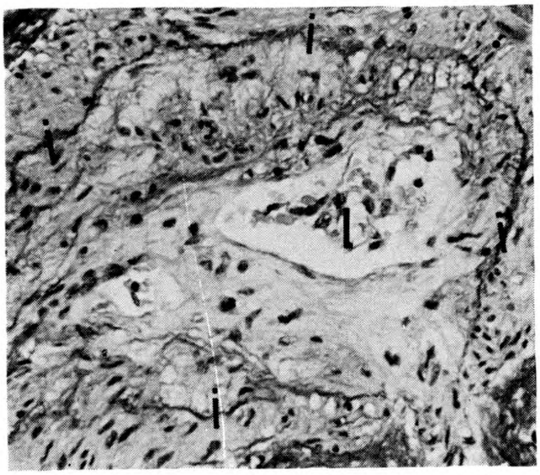

Fig. 14 *Same infant as in Fig. 13. Parent vessel of lesion shown in Fig. 13 is seen. There is obvious disorganisation of the architecture. Internal elastic lamina is outlined 'i' and indicates the approximate size of the original vessel lumen. New vessel lumen 'L' is considerably narrower. These appearances were interpreted as being due to recanalisation of the vessel after obliteration. HAEVG,* × *700.*

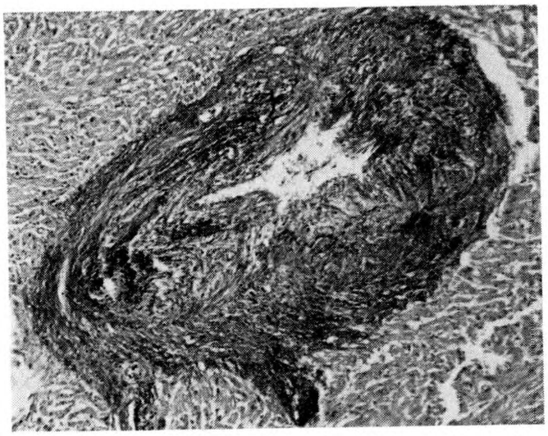

Fig. 15 *Complete destruction of architecture is seen in this section from the right ventricle of a 6-month-old infant, born at 39 weeks' gestation with an omphalocele which was repaired, but who required prolonged ventilation. Landmarks of the vessel wall are replaced by darkly-staining bands of elastotic scar tissue. Elsewhere in this section numerous normal vessels were found. HAEVG,* × *220.*

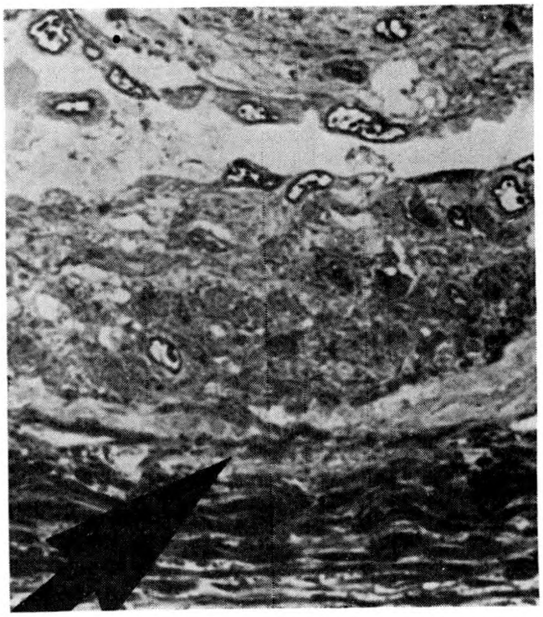

Fig. 16 *Intimal plaque in an intramural vessel from an infant age 99 days, born at 26 weeks' gestation, showing the cellular nature of the lesion and the obvious atrophy of the media (arrowed) under the point of maximum thickness of the plaque. Plastic-embedded, TB,* × *4000.*

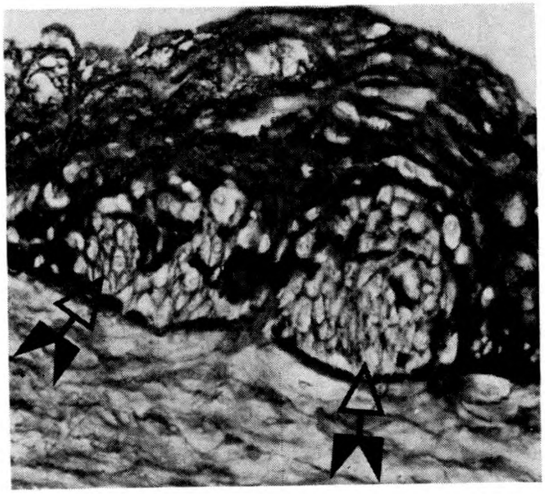

Fig. 17 *Small intimal plaque in anterior descending branch of coronary artery in 4-month-old 'sudden infant death'. Smooth muscle nodules (arrows) are present just above the internal elastic lamina, which shows up as an irregularly reduplicated layer. Aldehyde-fuchsine,* × *1000.*

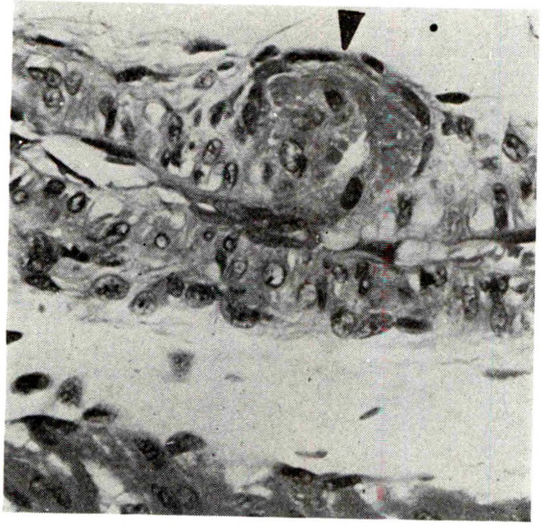

Fig. 18 *Intramural myocardial vessel from 2-month-old infant born at 40 weeks' gestation with severe birth asphyxia and with evidence of brain damage. A globular lesion (arrow) filled with fibrillary material, that stained positively for fibrin (not shown), is present. Media at this point of the vessel appear irregular and much less cellular than on the opposite side of the vessel wall section. Lesion was interpreted as a healed false aneurysm. Haematoxylin and eosin (H & E), × 1000.*

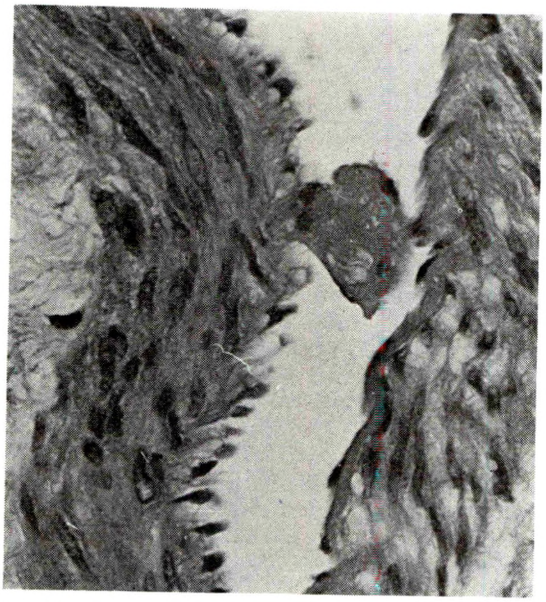

Fig. 19 *Organised, pedunculated, thrombus in an infant aged 32 days, born at 26 weeks' gestation. Lesion was seen in a branch of the circumflex artery. H & E, × 1000.*

In some of the older infants occasional zones of acute medial necrosis in both surface and intramural vessels could still be identified. This finding gave substance to the speculation that the degenerative changes seen in the older infants represented the end results of acute lesions seen in younger ones.

Some miscellaneous lesions were also identified. In one infant a rounded globular lesion contained fibrinous material, and was interpreted to be a healed false aneurysm (Fig. 18). Polypoidal structures in some larger vessels almost certainly represented organised thrombi (Fig. 19). Many of the smaller intramural vessels showed the presence of prominent foamy endothelial cells projecting into the lumen, and these were interpreted as representing a reaction to previous emboli.

Ultrastructural studies

In certain, selected cases, the 1 μm thick sections allowed the identification of zones of vacuolated smooth muscle cells in the walls of vessels which were severely damaged (Fig. 20) and representative samples from these areas were taken for ultrastructural studies. The cells themselves contained abundant lipid vacuoles, closely associated with

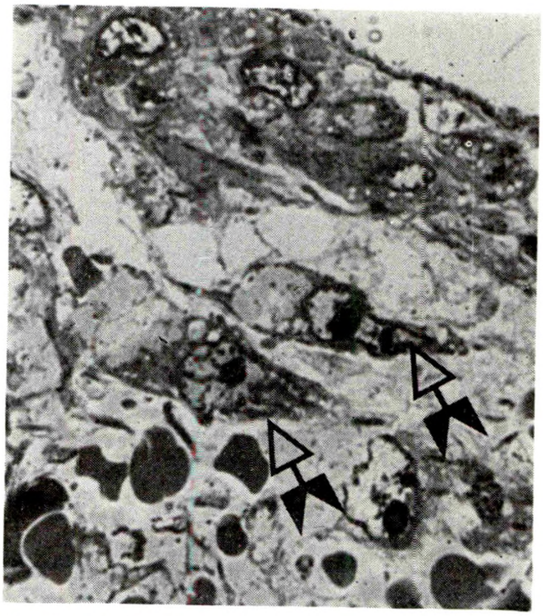

Fig. 20 *Section through an epicardial petechial haemorrhage from a stillborn infant of 42 weeks' gestation after a pregnancy complicated by abruptio placenta. granular endoplasmic reticulum, and many of the lipid vacuoles appeared to contain complex convoluted inclusions resembling myelin figures (Fig. 21). It was thought that these changes represent very early evidence of smooth muscle cell damage.

Associated clinical features. The frequency with which destructive lesions of the coronary arterial tree were found is shown in Table 2, and the high incidence in stillbirths, early neonatal deaths, infants maintained on prolonged ventilation, and sudden infant deaths is obvious. In the whole series nearly one-third of the infants had evidence of coronary arterial lesions.

The complications of pregnancy and postnatal life in the younger infants in this series are shown in Table 3. It can be appreciated that infants with necrotic and degenerative lesions of their coronary vessels were often associated with conditions that could lead to hypoxia both *in utero* and in postnatal life. In particular antepartum haemorrhage, fetal bradycardia, postnatal apnoeic attacks, respiratory distress syndrome, intraventricular haemorrhage, and any indication for prolonged ventilation were important associations.

*Most infants appear more than once.

In view of this apparent association with hypoxia, the clinical histories of the older infants (*not* maintained on prolonged ventilation) and the 'cot deaths' were reappraised. In particular, evidence of hypoxic episodes or conditions predisposing to hypoxia were searched for. These were present in 5 of the 13 'cot deaths' and in 6 of the 18 older infants (Table 4). Four of the 13 'cot deaths' were stated to have weighed 2500 g or less at birth. In 3 infants this was associated with maternal hypertension. In the remaining low birthweight infant no other associated anomaly of pregnancy was described. In the fifth 'cot death' there was a history of vaginal bleeding 3 days before delivery. In the 6 older infants, with anomalies of pregnancy and postnatal life, the clinical records were even less detailed than in the 'cot deaths'. Three were stated to have had apnoea at birth; 2 infants were said to have been 'premature' but no further details were given. One infant was

delivered by the breech with severe birth asphyxia, and also showed evidence of thalamic and brain stem neuronal loss at necropsy (at age 3 months). She was known to have had severe cerebral damage during life.

Findings in other vessels

Surprisingly, necrotic and proliferative changes of the variety described in the coronary arterial tree were not seen as commonly in the renal or adrenal vasculature (Table 5). When present in the microvasculature in these areas, they were almost invariably associated with thromboemboli associated with 'high placement' of an umbilical arterial catheter within the aorta, and several of these infants have been described elsewhere (Tyson *et al.*, 1976). In 5 infants the thromboemboli were probably derived from other sources: in 3 infants, fibrinous vegetations were present on both tricuspid and mitral valves. In the other 2 infants, thrombi were noted in pulmonary venules in association with bacterial pneumonitis.

Discussion

It has been known for a long time that the adequacy of the fetus' and infant's response to asphyxia to a great extent depends on the integrity of the cardiovascular system (Cross, 1966). If the cardiovascular system is damaged the fetus is compromised. In recent years interest in the myocardial function and reserve in perinatal hypoxia or asphyxia has been growing, and there is abundant evidence that in many instances the myocardium is affected in states of severe hypoxia (Burnard and James, 1961; Rowe and Hoffman, 1972; Rowe *et al.*, 1978). While this may reflect direct myocardial damage in hypoxia (de Sa, 1977), the possibility that damage to the coronary arterial tree may be an important factor does not appear to have been considered, and the earlier observations of Gruenwald (1949) have passed unnoticed. Yet it is clear, that in cases where there is frank myocardial necrosis (Bucciarelli *et al.*, 1977; de Sa, 1977) vascular lesions should be considered and sought for.

The data presented in this report show that coronary arterial lesions, albeit of a focal nature, are common in newborn infants, and that they are associated with myocardial necrosis. Owing to their focal nature, the arterial changes are not always easy to find and can be missed.

It is unlikely that the acute arterial lesions, described in this series of infants, represent the effects of resuscitation measures such as external cardiac massage. Not all our infants (with acute necrotic lesions) were resuscitated by this manner. While it is true that acute lesions were often more readily identifiable in surface vessels, many intramural vessels had similar changes. If it is suggested that the deep intramural vessels were damaged by external trauma, the insult must have been capable of producing exquisitely selective loss in the media of many vessels of varying calibre, while sparing many larger surface vessels and avoiding gross contusions of the myocardium. It is difficult to imagine such a model.

A far more convincing case can be made for the view that the many different arterial lesions seen in this small series of infants form part of a closely related spectrum. The sequence of events would include damage to the media, and in particularly severe cases to the intima, with the development of nonocclusive thrombi. Emboli could lodge in distal intramural vessels with varying degrees of myocardial damage. Repair of the initial vascular damage could explain the development of irregular medial scarring, with or without aneurysmal formation, and the striking intimal lesions seen in the intramural vessels could be traced to the organisation of thromboemboli. Such a sequence of events is known to occur in the vessels of other organs of humans (Salyer *et al.*, 1974; Sevitt, 1976; Tyson *et al.*, 1976), and animals (Allison *et al.*, 1967).

If the sequence of events outlined above is a correct interpretation, some of the earlier statements regarding 'remodelling' of the coronary arterial tree during growth of the fetus and infant need to be reassessed (Robertson, 1960; Ungar, 1965). During this study, numerous intramyocardial arteries were identified and examined closely. Most of them were perfectly 'normal' histologically without the evolution of longitudinal muscle bundles and other changes described by Ungar (1965). In the present series where deviations from the textbook 'normal' were identified, they were seen to be focal in nature and were often in close juxtaposition with 'normal'

LIBRARY

vessels of comparable calibre. As shown in Table 1 they were also often associated with myocardial lesions. One is tempted to agree with Wilens (1951) that most, if not all, intimal changes in any artery are due to pathological processes, and intimal changes in 'remodelled' vessels may be viewed in a similar fashion.

In this series there does not appear to be any relationship between the presence of coronary arterial lesions and a particular period of gestation or range of birthweight. It is easier to relate the lesions to the complications of pregnancy and postnatal life, and in particular to the likelihood of hypoxia or asphyxia that appears to represent the one factor common to them all.

It is well known that in infants dying from intrapartum asphyxia, epicardial and other serosal petechiae are common pathological findings at necropsy (Morison, 1970). The acute coronary arterial lesions presented in this paper were most readily identified in those hearts with epicardial petechiae, as Gruenwald (1949) pointed out earlier. In fact, what is thought to represent the very earliest evidence of arterial wall damage was seen near areas of ruptured, periarterial, epicardial capillaries. It is possible that some of the periarterial capillary vessels function as *vasa vasorum*. Certainly, retrograde injection of barium/gelatin mixtures into the ascending aorta with filling of the aortic sinuses and main coronary arteries delineate a delicate capillary network around the main coronary vessels and their larger branches (de Sa, unpublished observations). Rupture of these *vasa vasorum* could then produce the appearance of perivascular, epicardial petechiae. This, in turn, could lead to focal medial necrosis of the arterial wall, which could initiate the postulated sequence of events in the arterial wall.

Morison (1970) suggested that the serosal petechial haemorrhages seen at necropsy, in cases of intrauterine and intrapartum asphyxia associated with antepartum haemorrhage, were related to a great increase in the perfusing pressure in serosal capillaries. It is well known that in other situations an acute, rapid rise in blood pressure (as in the 'malignant' phase of hypertension) may be accompanied by evidence of bleeding due to destruction and rupture of the microvasculature (Goldby and Beilin, 1972). In experimental models, these areas of destruction are associated with fibrinoid necrosis (Allison *et al.*, 1967; Eto *et al.*, 1978). Similar changes are present in human material (Hughson and McManus, 1978). It is also known that in the human infant, one initial response to hypoxia or asphyxia is a sharp rise in blood pressure that may be related to catecholamine release (Dawes, 1968). It is permissible, therefore, to argue that in the asphyxiated baby a sharp rise in blood pressure, occurring as a reaction to the initial insult, may produce the rupture of epicardial vessels (Fig. 22).

For this explanation to be likely, however, it is necessary to explain the relative sparing of the visceral circulation (represented in this paper by the renal and adrenal vessels), for if the coronary vasculature is damaged by an episode of hypertension in response to an acute asphyxial insult, it would appear logical to expect lesions to be present in other viscera as well. The paradox can be explained only if it is postulated further that the splanchnic viscera, such as the adrenals and kidney, are 'protected' from the hypertension by a selective vasospasm. Such an explanation would be analogous to the discrepancy in the state of the arterial tree in the kidneys in cases of hypertension associated with unilateral renal artery stenosis. Here it is known that in the kidney supplied by the stenotic artery the arteries rarely show evidence of fibrinoid necrosis, while the arteries of the 'exposed' contralateral organ are severely affected (Heptinstall, 1966). One would expect that such a 'protective' vasoconstriction, while sparing the arteries, could make the organ prone to ischaemic damage. The association of haemorrhagic necrosis of the adrenal gland in stillbirths and infants with severe hypoxia/asphyxia *in utero* is well documented (de Sa and Nicholls, 1972), and presumably represents an example of this phenomenon.

It is possible, that if the initial asphyxial episode is severe and acute, and if the pressor response is pronounced there may be a considerable hazard posed to the fetus or newborn infant. It would be possible to construct a vicious cycle with a pressor

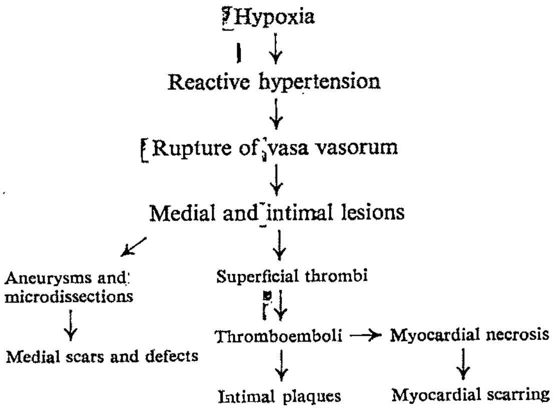

Fig. 22 *Suggested scheme for the development of necrotic and degenerative lesions of the coronary arterial tree in infants.*

response to hypoxia or asphyxia damaging the coronary arterial tree and affecting the myocardium secondarily. The damaged myocardium would be unable to respond adequately to the demands placed on it by the original insult, thereby deepening the metabolic complications of the asphyxia. Finally, poor coronary perfusion due to the myocardial damage (de Sa, 1977) would aggravate any original myocardial insult. If such vicious circles exist, extremely complex and severe anomalies of cardiac function could be expected. It was of considerable interest that at least some of the 'cot deaths' had myocardial and coronary arterial lesions strikingly similar to those infants with a well documented history of prolonged hypoxia. In fact, in some of these infants the clinical records suggested that hypoxic episodes had taken place. The findings are consistent, therefore, with some of the more recent views regarding the aetiology of 'cot (crib) deaths' (Naeye, 1973).

It is worth stressing the occurrence of coronary arterial changes in the newborn infant, irrespective of whether or not the pathogenesis of the lesions is known. They represent a serious hazard and may even help to explain how certain unusual lesions of the coronary arterial tree develop. Cases of medial calcification of the coronary vessels (Witzleben, 1970), occlusive fibroelastosis (MacMahon and Dickenson, 1967), coronary sclerosis (Jokl and Greenstein, 1944), congenital aneurysms (Gore *et al.*, 1959), and primary dissecting aneurysms of the coronary vessels in young adults (Whitehead and Dunnill, 1969), could all have their origin in the lesions described in this report. In most of these reported cases, it is difficult to trace any direct connection with anomalies of the antenatal and postnatal period, since details on these points are often scarce, not available, or not even considered. This is not entirely surprising, but in any future studies of coronary vessels in infants and children, it would be useful to ascertain as much information as possible regarding the antenatal and postnantal periods of development.

Finally, while it is clear that the lesions of the coronary artery can heal, it is equally likely that once damaged no vessel will remain perfectly normal, and it is tempting to suggest that small scars of the coronary arterial tree could predispose to the more severe plaques of later life.

I am grateful to many colleagues in the Department of Pathology and the Hamilton District Program in Laboratory Medicine for access to their material and other help, and to Sharryn Putns, Marion Leskovec, Stephanie Whittaker, and George Turcon for excellent technical assistance.

Assessment of individual renal function in children using ^{99m}Tc-DTPA

G. KAINER, B. MCILVEEN, R. HÖSCHL, AND A. R. ROSENBERG

Department of Nuclear Medicine, and Division of Nephrology, Prince of Wales Children's Hospital, New South Wales

SUMMARY Differential renal function assessment using ^{99m}Tc–DTPA was carried out in 12 children aged between 3 weeks and 11 years who had undergone surgical procedures which allowed separate access to the urine output from each kidney. The results correlated well with those obtained by measuring individual kidney creatinine clearances. The best result was obtained using the technique of deconvolution analysis ($r = 0 \cdot 98$; $P<0 \cdot 001$). We conclude that the method is accurate and recommend its use in the management and follow-up of patients with asymmetric renal disease.

The need for a reliable noninvasive method for studying individual kidney function in children is apparent. The damage incurred by the kidneys in diseases such as vesicoureteric reflux and obstructive uropathy is seldom symmetrical, and the selection of optimal treatment and follow-up requires quantitative information about the functional status of each kidney as well as knowledge of the total renal function. An example of the type of case in which such information would be useful is that of a child with bilateral reflux nephropathy who has poor function of one kidney on intravenous urography. A decision has to be made as to whether ureteric reimplantation or nephrectomy should be carried out. It would obviously be advantageous if the relative function of the affected kidney could accurately be assessed.

Radiographic contrast techniques give valuable information about the anatomical structure of the kidneys and collecting systems. However, they provide only qualitative information on differential renal function. Bilateral ureteric cannulation for the measurement of individual kidney clearances carries the risk of introducing infection and requires general anaesthesia, and is therefore not suitable for routine use.

Attempts have been made for some time to assess individual renal function by noninvasive radioisotope techniques (Johnston and Irving, 1967; Kathel, 1971), and more recently methods using technetium-labelled stannous diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) have been described (Pieretti *et al.*, 1974; Nielsen *et al.*, 1977). The use of deconvolution analysis to quantify the renogram and the potential advantages of this method in radioisotopic assessment of renal function have been described by Kenny *et al.* (1975) and Diffey *et al.* (1976).

A method for quantitating individual renal function using ^{99m}Tc-DTPA has recently been described by Piepsz *et al.* (1977), but nonradioisotopic measurements of individual renal function were not carried out and it is therefore difficult to judge the accuracy of the technique.

The purpose of this study was to determine the accuracy of individual renal function measurements in children using ^{99m}Tc-DTPA.

Methods and materials

The 12 children studied were aged between 3 weeks and 11 years (Table 1). Informed parental consent was obtained in each case. All had undergone surgical procedures which allowed separate access to the urine output from each of their kidneys—that is, they had ureterostomies or indwelling ureteric splints. Renal function assessments were carried out at least 6 days after surgery.

Urine was collected from both kidneys simultaneously for a period of not less than 6 hours, and plasma creatinine was estimated on a blood sample taken at the time of the urine collection. All creatinine estimations were done using the auto-

analyser (6–60 Technicon). To establish the stability of the patient's renal status, two plasma creatinine estimations a day apart were performed. Individual kidney creatinine clearances were derived using the standard formula clearance = U.V/P (where U = concentration of creatinine in urine, V= volume of urine collected per minute, P= plasma creatinine concentration). The contribution of the left kidney was expressed as a percentage of the sum of the creatinine clearances of the two kidneys.

No limitations on food and drink were imposed during the estimation of creatinine clearance or before scanning, and none of the patients was receiving intravenous fluids. Scans were performed within 24 hours of creatinine clearance estimations. All the children were recumbent for at least one hour before scanning. Premedication was not routinely given beforehand, but some children required a small dose of diazepam immediately before injection of the radiopharmaceutical. To allay anxiety the parents were asked to be present during the test.

An intravenous dose of 3·7 megabecquerels (100 μCi) per kg of ^{99m}Tc-DTPA (supplied by the Australian Atomic Energy Commission) was injected as a bolus. The children lay on a foam rubber pad placed directly on the gamma camera head (Nuclear Chicago Pho-Gamma III HP Camera with low energy, high sensitivity parallel hole collimator). Data were recorded by a computer (DEC Gamma—11 system) at the rate of one frame per 5 seconds for a total of 200 frames.

Analogue scans were recorded on Polaroid and 70 mm films for one minute after the injection (one exposure every 5 seconds), followed by renal scan image (taken at a preset count of 300 000). For computer processing, regions of interest were drawn manually as close as possible to the renal outlines using a 'joystick'. In each subnephric area a background region of interest was chosen, care being taken to avoid the course of the ureters and large vessels. Another region was selected over the heart in order to generate the blood activity (heart) curve (Figs 1 and 2).

Counts for each kidney were corrected for background after the background area was normalised to the area of the ipsilateral kidney. The 120-second net counts for each kidney were integrated over the time intervals 1–3 minutes, 2–4 minutes, and 13–15 minutes. Background corrected time activity curves were displayed (Fig. 3).

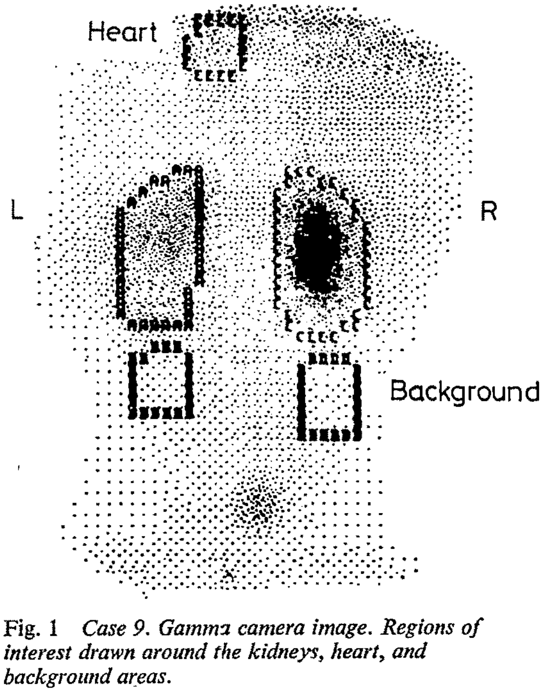

Fig. 1 *Case 9. Gamma camera image. Regions of interest drawn around the kidneys, heart, and background areas.*

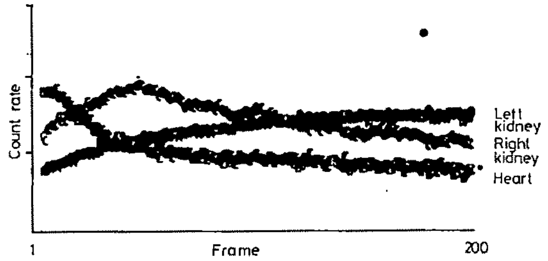

Fig. 2 *Case 9. Renograms and heart curve. Right kidney curve normal. Left kidney curve shows impaired renal function.*

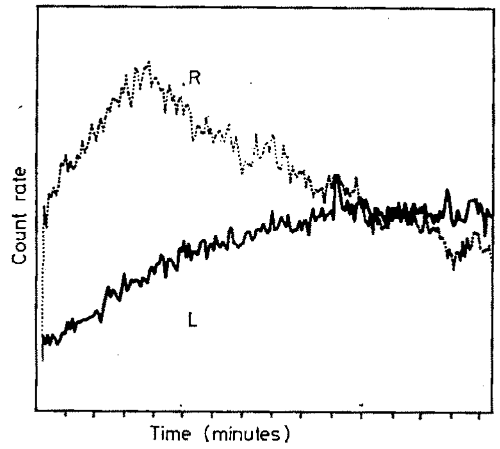

Fig. 3 *Case 9. Renograms after background subtraction. Right (R) kidney curve normal. Left (L) kidney curve shows impaired renal function.*

The percentage uptake of radioactivity for the left kidney was calculated by dividing the net counts for that kidney by the sum of the net counts from both kidneys—that is L/(L + R) × 100. The results for the three time intervals were compared with the percentage contribution of the left kidney to the total creatinine clearance (Figs 5a, 5b, 5c).

Deconvolution analysis with data bounding (Diffey and Corfield, 1975; Valentinuzzi and Montaldo Volachec, 1975) was used to plot the retention function for each of the kidneys. The retention function is the form that the renogram would take if a bolus of ^{99m}Tc-DTPA could be injected directly into the renal artery (Fig. 4). The amplitudes of the retention function curves were used to calculate the relative uptake of radioactivity by the left kidney as compared with the total, and the results compared with those obtained from creatinine clearances (Fig. 5d).

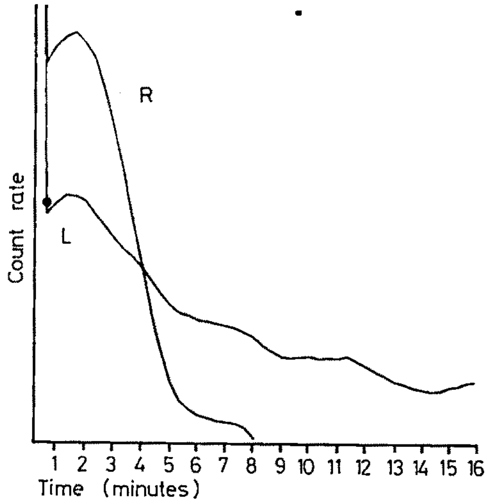

Fig. 4 *Case 9. Retention function curves derived from deconvolution analysis with data bounding. Right (R) kidney curve normal. Left (L) kidney curve shows impaired renal function.*

Correlation coefficients were derived by comparing the results obtained from scanning with those obtained from creatinine clearance estimations (Fig. 5).

95% confidence limits were determined for the results obtained from scanning methods at 1–3 minutes, 2–4 minutes, and by deconvolution analysis. Two points were chosen for determination of confidence limits—namely, where the left kidney contribution to the total renal function was 10 and 90% (Table 2).

Results

The data are presented in Table 1. The contribution of the left kidney to the total creatinine clearance,

*Regression analysis.

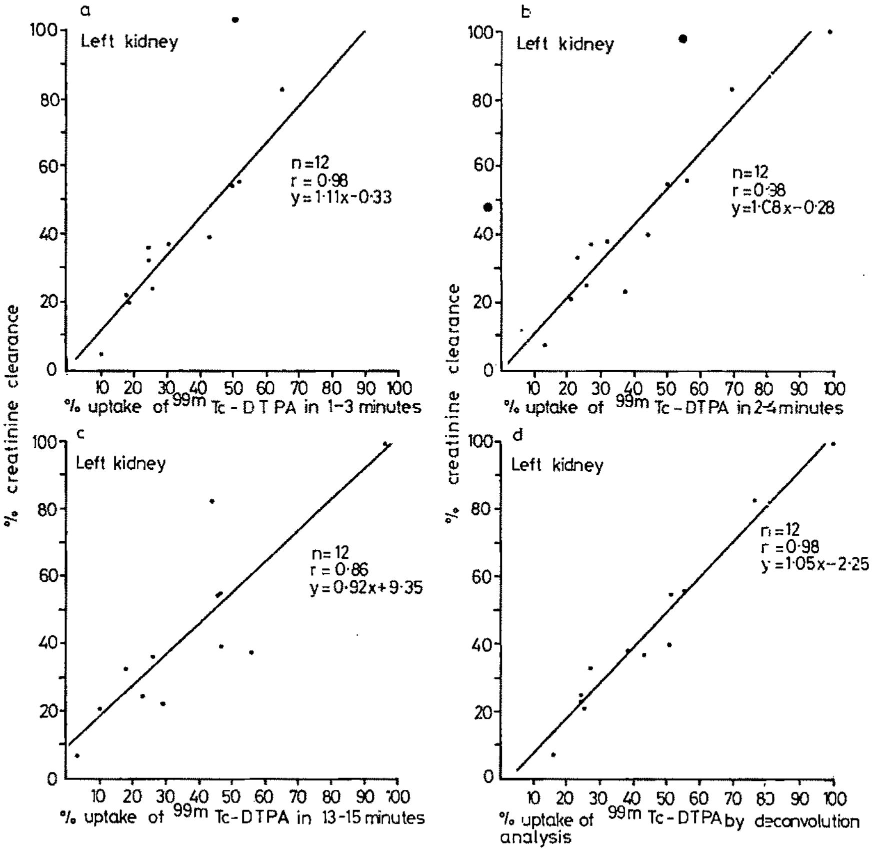

Fig. 5 *Left kidney. Percentage of total creatinine clearance v. percentage of total renal uptake of ^{99m}Tc-DTPA (a) in 1–3 min, (b) in 2–4 min, (c) in 13–15 min, (d) by deconvolution analysis.*

when compared with the results obtained using radioisotopic techniques, showed a high degree of correlation (r= 0·98) with the 1–3 minute and 2–4 minute kidney uptake ratios and with the deconvolution analysis technique. A lower correlation (r= 0·86) was found at the 13–15 minute interval. All were significant ($P<0·001$).

The mean disparity between the scan results and those obtained from creatinine clearances was 6% for the 1–3 minute, 5% for the 2–4 minute, and 11% for the 13–15 minute uptake ratios, and 4% for the deconvolution analysis method.

The calculated predictions for left renal function from the data, using regression analysis, are presented in Table 2.

Discussion

The required characteristics of any substance for the measurement of glomerular filtration rate (GFR) are: (1) It must be preferentially excreted by the kidney. (2) It must be freely filtered through the glomerular basement membrane. (3) It must be physiologically inert. (4) It must not be reabsorbed or secreted by the renal tubules.

The classical substance fulfilling the above criteria is inulin (Materson, 1971). However, determination of inulin concentration is difficult and the technique does not lend itself to routine hospital use. Inulin is not readily labelled by available gamma-emitting radionuclides of suitable energy, radiation, or half-life. One of the newly developed substances with physiological characteristics closely resembling those of inulin is DTPA (Reba *et al.*, 1974; Barbour *et al.*, 1976). This chelating agent can be readily labelled with various radionuclides, including ^{99m}Tc. The resulting complex is suitable for radioisotopic determination of GFR (Hauser *et al.*, 1970; Chevru *et al.*, 1974).

^{99m}Tc has ideal physical characteristics for application in nuclear medicine. It has a short half-life (6 hours) and suitable radiation characteristics (140 keV photons in 90% abundance and no beta radiation). The 140 keV photon has adequate tissue penetration and is efficiently measured by the current generation of gamma cameras. Its low radiation dose permits repeated examinations in children (Chevru *et al.*, 1974; Kirchner *et al.*, 1975).

The ^{99m}Tc-DTPA complex, after intravenous injection, equilibrates rapidly throughout its extracellular distribution space. It is cleared through the glomeruli without appreciable tubular secretion or reabsorption and only 5% is excreted in the faeces. More than 98% of the radioactivity remains in the chelated form and only 5–10% of the serum radioactivity at one hour after injection is associated with serum proteins (Hauser *et al.*, 1970; Arnold *et al.*, 1975).

This study demonstrated that individual renal function in children can accurately be assessed using ^{99m}Tc-DTPA and external monitoring with computerised quantitation. The deconvolution analysis method gave the best results, but the 1–3 minute and 2–4 minute kidney uptake ratios were also satisfactory.

Statistical testing of the accuracy of these methods at the extremes of renal function—that is 10 and 90% function in one kidney, gave results quite adequate for clinical use (Table 2). The best methods for measuring GFR have an accuracy of ± 3–6% (Materson, 1971). 10 and 90% levels of individual renal function were chosen because it is at these levels of relative function that decisions regarding nephrectomy are most often made.

On computer analysis of the gamma camera data, it is essential to draw the regions of interest as closely as possible around the renal outlines; this is particularly important for the relative uptake method. Inclusion of extrarenal areas tends to reduce the average count in each matrix element. For the deconvolution analysis method the selection of a region of interest close to the kidney outline is not as critical, provided it includes all functioning renal parenchyma.

All the children were recumbent for at least one hour before and during the time of scanning. This was felt to be important as changes in posture may lead to alterations in urodynamics and haemodynamics. The positioning of the child on top of the collimator made venepunctures easier and was found to be less frightening for the child than prone with the gamma camera head suspended above.

It was found that background regions of interest were most representative in the subnephric regions. Other sites such as areas lateral to the kidneys were found to be technically unsatisfactory in smaller children with hydronephrosis. In one child (Case 6, Table 1) with unilateral renal agenesis, the counts obtained in the subnephric area virtually equalled the counts obtained from the site where the kidney would normally have been situated.

Apart from its use in determination of individual renal function, scanning with ^{99m}Tc-DTPA may also be helpful in the demonstration of anatomical abnormalities of the kidneys and collecting systems, and in the diagnosis of urinary obstruction. Obstruction to urine outflow can be inferred from the shape of the renogram and from the retention function curve after deconvolution analysis (left kidney; Figs 3 and 4). Retention of radioactive material due to obstruction is best assessed by the net cumulative count at the 13–15 minute time interval (for example, Case 8, Table 1).

In summary, we have shown that assessment of individual renal function with ^{99m}Tc-DTPA in children is accurate. It carries less risk and is no more disturbing to the child than a comparable radiological investigation. It can be done in any hospital with a modern nuclear medicine department. We believe that the use of this technique will prove to be important in the management and follow-up of patients with asymmetric renal diseases and also in the understanding of the evolution of these disorders.

We thank Professor G. F. Murnaghan and Dr R. H. Farnsworth for allowing access to patients, and Dr G. Southon for computer programming assistance.

TSH and PRL response to thyrotrophin-releasing hormone in children with chronic renal failure undergoing haemodialysis

KUNLE IJAIYA

Department of Paediatrics, University of Cologne

SUMMARY Eight children (aged between 8½ and 15½ years) with chronic renal failure receiving intermittent haemodialysis, and 2 children with renal transplants were studied. The response of TSH and prolactin (PRL), and basal T4 and T3 values was measured. Basal TSH was normal, and rose only slightly after TRH stimulation. Plasma T4 and T3 were below normal levels in 6 children. Mean basal PRL was raised and could not be stimulated by TRH. This study demonstrates the involvement of the hypothalamus and pituitary in chronic renal disease. The cause of the abnormal secretion of TSH and PRL in chronic renal failure is discussed in the light of clinical importance.

Pituitary, thyroid, and gonadal hormones are important in the growth, skeletal, and sexual maturation of children. Endocrine abnormalities have been reported in patients with chronic renal failure (Feldman and Singer, 1975), in whom synthesis, secretion, and degradation of the affected hormones and their activity on target organs are impaired. In uraemic children, endocrine abnormalities have been observed by Czernichow *et al.* (1976) and Ijaiya *et al.* (1978), but information in this age group is scanty.

The present study was undertaken to assess hypothalamic and pituitary functions in children with chronic renal disease.

Patients and methods

Eight children with chronic renal failure (CRF) undergoing haemodialysis for 1 to 86 months, and 2 children who had had successful renal transplants 25 and 44 months earlier were investigated. Clinical details are shown in Table 1. Haemodialysis was generally performed for 6 hours 3-times a week.

No child showed galactorrhoea or gynaecomastia and no thyroid disease had been diagnosed. The aims of the study were explained to the patients and their parents and their informed consent was obtained. 22 (12 girls and 10 boys) healthy children, aged between 8 and 15 years, in hospital because of their short stature served as a control group. Five of these children have achieved almost complete sexual maturation, the rest were prepubertal. They were in

good health and endocrine studies showed no abnormality.

Synthetic TRH (Relefact TRH, Hoechst AG, Frankfurt) was administered intravenously at a dose of 200 µg dissolved in 2 ml saline. All children were fasted overnight and remained in bed before and during the test. The test was performed at least 18 hours after haemodialysis. Blood samples were withdrawn through an indwelling cannula in an arm vein at 0, 15, 30, 45, 60, 90, and 120 minutes after TRH injection. Heparinised blood was immediately centrifuged at 4°C, and the plasma stored at −20°C until assayed for TSH, PRL, T4, and T3. Plasma TSH was determined by a double antibody radioimmunoassay (Utiger, 1965) (Amersham Buckler, Düsseldorf, Germany) (normal value, 0–7 µU/ml); plasma PRL by the double antibody method of Reuter *et al.* (1976) (Union Carbide, Sleoros, Belgium) (normal 6–10 ng/ml); plasma T4 by a competitive protein-binding radioassay (Res-O-Mat T4, Byck-Mallinchrodt Co, Dietzenbach, Germany) (normal 4·5–11·4 µg/100 ml), and T3 by radioimmunoassay (T3 RIA-KIT, Serono, Freiburg, Germany) (normal 0·6–1·7 ng/ml).

Statistical evaluations were by the Wilcoxon, Mann and Whitney U test for unpaired groups.

Results

Mean plasma concentration and SDs for basal TSH, PRL, T4, and T3 in controls and in children with CRF are shown in Table 2 which also shows the peak levels after TRH stimulation. The range of values and the results in the children with transplants are shown in Figs 1 and 2. No significant difference in basal levels of TSH, T4, or T3 was found. However, 6 of the 8 children with CRF had T3 or T4 levels below the normal range; PRL basal levels were significantly higher in the children with CRF failure. Basal levels were within the normal range in the children with transplants. After TRH stimulation, TSH rose in both groups with a peak response >8·0 µU/ml. In 5 cases TSH values had not fallen to basal levels 90 minutes after TRH injection. PRL levels after TRH stimulation rose in the control children, but were not significantly different from basal levels in children with CRF. Case 3, who was receiving medication for acute hypertension (Table 1) and who had been on dialysis for only one month, had a normal basal PRL level (4·8 ng/ml) with only a slight rise after TRH. Sex, puberty, or duration of haemodialysis had no influence on the raised basal

level of plasma PRL, or on the failure to increase PRL concentration after TRH injection in children with CRF.

Discussion

Studies of thyroid function in patients with CRF have produced conflicting results; both hyperthyroidism (Schmidt *et al.*, 1971) and hypothyroidism with low T3 and T4 levels have been reported (Ramirez *et al.*, 1972; Czernichow *et al.*, 1976; Kølendorf *et al.*, 1978). Raised plasma-free thyroxine was reported by Bailey *et al.* (1967) in dialysed patients, and after successful renal transplants these parameters returned to normal. Heparin administration during haemodialysis raises levels of free T4, but not total T4 (Schatz *et al.*, 1969).

The thyroxine-binding capacity of TBG in chronic renal failure is normal (Joasso *et al.*, 1974; Kølendorf *et al.*, 1978), whereas the binding capacity of thyroxine-binding prealbumin is low (Jaffiol *et al.*, 1970). Joasso *et al.* (1974) suggested that the change in serum T4 was due to some unidentified substance, which displaces T4 from TBG in serum of patients with renal failure. TSH, T4, and T3 are not dialysable (Bindeballe *et al.*, 1973; Silverberg *et al.*, 1973). Impairment of the peripheral conversion of T4 to T3 was also suggested (Lim *et al.*, 1977). Normal ^{131}I uptake after stimulation of thyroid with TSH in dialysed patients has been reported (Silverberg *et al.*, 1973).

Except in cystinosis, primary thyroid disease is unlikely to be responsible for the low levels of thyroid hormones (Burke *et al.*, 1978). TSH production might be expected to be stimulated by low levels of thyroid hormones, and raised basal value of serum TSH in dialysed patients has been reported (Waldhäusl *et al.*, 1971); others have found normal (Czernichow *et al.*, 1976) or low values (Silverberg *et al.*, 1973). Basal TSH was normal in our patients.

Despite low serum thyroid hormones and normal basal TSH level, exogenous TRH could not stimulate pituitary TSH release, suggesting a defect in pituitary secretion of TSH (Ramirez *et al.*, 1972; Silverberg *et al.*, 1973). The negative feedback mechanism seems, however, to be intact, for high dosages of T3 lowered TSH (Czernichow *et al.*, 1976). The cause of the pituitary abnormalities in these patients is unknown; severe malnutrition or uraemic toxins may be involved (D'Angelo, 1951; Feldman and Singer, 1975).

A trial of thyroid hormone replacement in dialysed uraemic patients with low serum T4 levels and clinical symptoms of hypothyroidism gave inconsistent results (Silverberg *et al.*, 1973). Chan *et al.* (1970) reported a 10-year-old boy with CRF and clinical signs of hypothyroidism who showed an increase in height velocity after starting thyroid extract. Increased growth velocity with thyroid supplementation occurred in only 2 out of 7 patients treated by Burke *et al.* (1978). An improvement in growth and better pubertal development may be achieved with thyroid hormone replacement.

An abnormal response of PRL to TRH, with raised basal PRL which could not be stimulated after TRH injection has been reported in uraemic patients (Czernichow *et al.*, 1976; Archer, 1977; Sciarra *et al.*, 1977). Despite the increased PRL, no galactorrhoea or gynaecomastia was observed. The high prolactin may be responsible for the hypogonadism or amenorrhoea in several patients (Thorner, 1977). Whether the hyperprolactinaemia in the uraemic child affects gonadal maturation, and therefore delay in puberty, needs further clarification. The cause and clinical importance of the raised PRL are still poorly understood. High PRL levels are found in primary hypothyroidism (personal observation) often combined with the triad galactorrhoea, precocious puberty, and hypothyroidism (van Wyk and Grumbach, 1960). None of our patients exhibits clinical signs of hypothyroidism. The abnormal TSH response to TRH would even suggest a secondary hypothyroidism. In our patient receiving medication for acute hypertension PRL secretion was normal. This is despite the fact that several drugs—such as reserpine and α-methyldopa—have been found to increase serum PRL levels (Archer, 1977; Thorner, 1977).

The source of high PRL values in uraemic patients is still unknown. A loss of renal degradation cannot be the only cause, several other peptide hormones are not raised. Cowden *et al.* (1978) demonstrated a progressive rise in PRL concentrations as renal function deteriorates, and a return to normal after successful renal transplants. PRL is supposed to have a fundamental osmoregulatory role in many species of fish and amphibians (Lam, 1972). Its possible role as an osmoregulator in man remains controversial. The role of the hypothalamus and pituitary in the abnormal secretion of PRL is obscure. Since increased PRL secretion is due to a decrease in hypothalamic prolactin-inhibiting factor or an increase in prolactin-releasing factor (L'Hermite *et al.*, 1974), a dysfunction of the hypothalamus may result in decreased prolactin-inhibiting factor or increased prolactin-releasing factor biosynthesis or secretion.

This study has demonstrated the involvement of the hypothalamus and pituitary in children with CRF. Levels of T3 and T4 tend to be low and this is due to inadequate TSH production. PRL is high, but the pituitary reserve is limited so it does not rise further after TRH stimulation. The renal cause of the hypothalamic-pituitary dysfunction remains poorly understood.

Persistent pulmonary hypertension and abnormal prostaglandin E levels in preterm infants after maternal treatment with naproxen

ANDREW R. WILKINSON, A. AYNSLEY-GREEN, AND M. D. MITCHELL

Department of Paediatrics and Nuffield Department of Obstetrics, John Radcliffe Hospital, Oxford

SUMMARY Twins and a singleton were born at 30 weeks' gestation although naproxen (d-2 (6'methoxy-2-naphthyl) propionic acid) had been given to the mothers in an attempt to delay parturition. Inhibition of prostaglandin synthesis was shown by very low plasma concentrations of prostaglandin E and the ductus arteriosus remained closed despite signs of pulmonary hypertension with severe hypoxaemia. Abnormalities in blood clotting, renal function, and bilirubin metabolism were also found and one infant died. Further studies of the benefits and risks of the inhibition of prostaglandin synthesis are required before this treatment of preterm labour is accepted.

Indomethacin and salicylates are prostaglandin synthetase inhibitors (PGSI), which suppress uterine activity in animals and humans (Wigvist *et al.*, 1975). Some workers have used PGSI to treat women after the onset of preterm labour (Zuckerman *et al.*, 1974), but experiments in lambs (Heymann and Rudolph, 1976; Levin *et al.*, 1979) show that these drugs cross the placenta and cause great changes in the fetal circulation with closure of the ductus arteriosus and an increase in pulmonary arterial pressure. Postnatal persistent pulmonary hypertension has been described after maternal treatment with indomethacin and salicylates (Manchester *et al.*, 1976; Csaba *et al.*, 1978; Levin *et al.*, 1978). We report 3 premature infants with this syndrome who were born to mothers who had been given naproxen (d-2 (6'methoxy-2-naphthyl) propionic acid) which is another potent PGSI.

Case 1

A girl weighing 1·28 kg was born at 30 weeks' gestation to a 28-year-old mother. There had been recurrent vaginal bleeding throughout pregnancy and at 28 weeks uterine contractions became frequent. Naproxen 250 mg was given orally 8-hourly for 6 days and contractions became less frequent but 48 hours after stopping naproxen spontaneous labour recurred. The baby was delivered by caesarean section because of breech presentation. The Apgar score was 2 and the baby was resuscitated with oxygen and positive pressure ventilation, but cyanosis persisted and tachypnoea developed. Artificial ventilation was continued and at 40 minutes while breathing 50% oxygen arterial pH was 7·04, Pa_{O_2} 3·0 kPa (23 mmHg), and Pa_{CO_2} 7·9 kPa (59 mmHg). Breath sounds were normal and no heart murmurs were heard. The haematocrit was 52% and blood glucose concentration normal. Parenchymal and vascular markings and the heart size were normal on chest *x*-ray. The inspired oxygen concentration was raised to 100% and ventilation pressure to 30 cmH_2O with 4 cmH_2O end-expiratory pressure. Fig. 1 shows that despite these changes, the Pa_{O_2} could not be raised above 6·7 kPa (50 mmHg) until 6 hours after birth. At 10 hours, right radial and umbilical artery blood-gas tensions were identical (Fig. 1). She required assisted ventilation until 63 hours of age and additional oxygen until the fifth day. There was no evidence of pneumonia, hyaline membrane disease, or aspiration. Urine was not passed until 24 hours and plasma bilirubin rose to 252 μmol/l (14·7 mg/100 ml). Bleeding time was prolonged but platelet count and clotting studies were within normal limits. At discharge, age 61 days, she weighed 2·2 kg and examination was normal.

Effect of tolazoline hydrochloride is shown in Cases 2 and 3. S = identical gas tensions in umbilical and right radial arterial blood and blood samples taken for prostaglandin assay. Conversion: SI to traditional units* 1 kPa ≈ 7·5 mmHg

Cases 2 and 3

Twin girls were delivered by caesarean section at 30 weeks' gestation to a 20-year-old mother after a pregnancy complicated by vaginal bleeding and preterm labour. 30 hours before delivery naproxen 250 mg 8 hourly had been begun. A total of 1 g was given, the last dose 5 hours before delivery.

The first twin weighed 1·18 kg. The Apgar score was 1 and positive pressure ventilation was given immediately. At 30 minutes while breathing 80% oxygen arterial pH was 7·05, Pao_2 6·7 kPa (51 mmHg), and $Paco_2$ 10·8 kPa (81 mmHg). The lung fields were clear and the heart size normal on chest *x*-ray. Haematocrit and blood glucose concentration were normal and the lecithin/sphingomyelin ratio (L/S) was 2·0 in the pharyngeal aspirate. The hypercarbia was rapidly corrected by artificial ventilation but Pao_2 remained low despite pressures up to 35 cmH_2O and 100% oxygen. Simultaneous right radial and umbilical blood-gas tensions taken when the baby was unresponsive were identical at 40 hours (Fig. 1). Tolazoline hydrochloride (2 mg/kg, IV) produced an immediate improvement in oxygenation (Fig. 1) which was maintained by an infusion (2 mg/kg per hour) for 20 hours. Assisted ventilation was necessary for 5 days after which chronic lung disease with oxygen dependency persisted for 12 weeks. During the first 2 days plasma bilirubin rose to 225 µmol/l (13·2 mg/100 ml) and bleeding time, prothrombin time, and partial thromboplastin time were prolonged. Urine volume was markedly reduced until the third day.

The second twin was delivered 2 minutes later and weighed 1·26 kg. The Apgar score was 1 and severe hypoxaemia rapidly developed. Treatment and investigations were similar to those in the first twin. The L/S ratio was 3·1, and within the first 24 hours the bilirubin rose to 230 µmol/l (13·5 mg/100 ml). Bleeding from the umbilical stump and heel punctures was prolonged and the clotting studies were abnormal. At 3 hours an intracranial haemorrhage was suspected. At 10 hours tolazoline hydrochloride (2 mg/kg, IV) rapidly improved oxygenation (Fig. 1) and during the next 60 hours ventilatory assistance was gradually withdrawn. However, at 80 hours she suddenly became apnoeic with a distended abdomen and poor peripheral perfusion. Cardiac arrest occurred and resuscitation was unsuccessful. Necropsy showed a subarachnoid haemorrhage and blood in both ventricles. Multiple gastric ulcers were present and there was blood throughout the intestine. The ductus arteriosus was short and constricted and hyaline membranes were not seen in sections of the lungs.

Assay of plasma prostaglandins. The plasma concentrations of prostaglandins E and F (PGE and PGF), and 13, 14-dihydro-15-keto-PGF (PGFM) (the major circulating metabolite of PGF), were measured by methods described previously and in Fig. 2 the values at 10, 40, and 10 hours age are compared with the levels found in preterm infants of the same age who were not ill (Mitchell *et al.*, 1978).

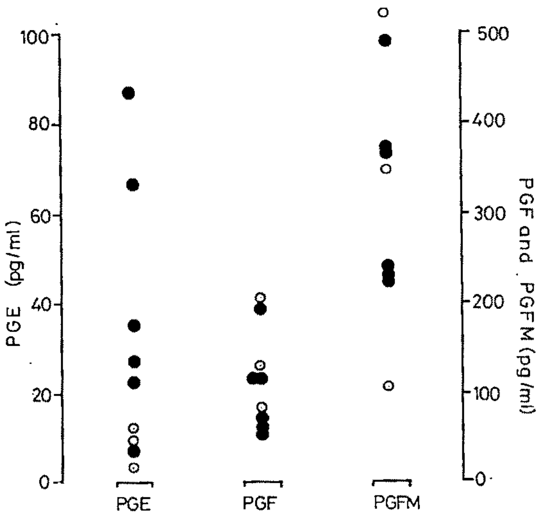

Fig. 2 *Plasma concentration of PGE, PGF, and PGFM (pg/ml) (open circles), compared with concentrations in preterm infants without cardiopulmonary disease (closed circles).*

Discussion

Persistent pulmonary hypertension presents during the first hours of life with arterial oxygen desaturation in the absence of parenchymal pulmonary disease or cardiac malformation. The mechanisms responsible are not known but an altered structure or abnormal response of the smooth muscle of the pulmonary arterioles has been suggested (Levin *et al.*, 1978). The condition has been associated with birth asphyxia, hypoglycaemia, hypocalcaemia, and hyperviscosity. The 2 infants who survived (Cases 1 and 2) were not hypoxaemic at birth. Umbilical cord vein Po_2 was 4·1 and 2·9 kPa (31 and 22 mmHg). In Case 3 the umbilical cord was so friable that blood could not be obtained. Undoubtedly hypoxaemia after birth contributed to maintaining the high pulmonary vascular resistance. Cassin *et al.* (1978) showed that this effect of hypoxia is potentiated by indomethacin and meclofenamate (another PGSI). In their experiments with goats the response to indomethacin was more pronounced in the premature than mature newborn. They also reported than an infusion of PGE abolishes the response to hypoxia and can reverse the effect of the PGSI.

Constriction of the ductus arteriosus and pulmonary arterial hypertension after maternal indomethacin administration in fetal lambs has been reported by Levin *et al.* (1979). This effect was also reversed promptly but temporarily by an infusion of PGE. In the 3 infants described here the identical gas tensions in blood drawn simultaneously from both sides of the ductus arteriosus (Fig. 1) and the absence of a ductal flow murmur suggests that the ductus arteriosus had constricted. The very low concentrations of prostaglandin E in all 3 babies (Fig. 2) supports the view that this prostaglandin plays an important role in maintaining relaxation of the ductus arteriosus *in utero* and that constriction may follow inhibition of prostaglandin synthesis.

The association between pulmonary hypertension and inhibition of prostaglandin synthesis in humans was first suggested by Manchester *et al.* (1976) who described 2 cases after treatment with indomethacin, and the report by Zuckerman *et al.* (1974) included 5 infants who died within 48 hours. Csaba *et al.* (1978) reported 2 deaths in 5 infants after indomethacin and Levin *et al.* (1978) reported 2 deaths, one each after salicylate and indomethacin treatment, in which they found an increase in pulmonary arterial smooth muscle and a decrease in the number of pulmonary vessels. This report is the first to implicate naproxen in a similar role.

When the severe hypoxaemia of the twins (Cases 2 and 3) was refractory to other treatment we gave tolazoline hydrochloride which caused a large rise in Pao_2 (Fig. 1). There was a pronounced skin flush and fall in systolic blood pressure from 58 to 35 mmHg and 69 to 39 mmHg which was restored immediately by infusing albumin and blood. Tolazoline is a potent pulmonary and systemic vasodilator and blood pressure must be continuously monitored to detect severe hypotension. The gastric ulceration and bleeding found at necropsy (Case 3) was probably due to the histaminic action of tolazoline on gastric secretion. It is less certain whether the cerebral bleeding preceded the infusion of tolazoline or not.

The role of naproxen in the aetiology of early hyperbilirubinaemia, the abnormalities in blood clotting, and the impairment of renal function remain to be defined.

There is no universally effective and safe way of delaying preterm labour, and only when details of all the effects of PGSI are known will it be possible to decide whether there is any benefit to the fetus from this form of treatment. At present the possible hazards outweigh the theoretical advantage taking into account the improved prognosis for premature infants with current management.

We thank Professor F. Dray (Pasteur Institute, Paris) for prostaglandin antisera, Dr J. E. Pike (Upjohn Company, Kalamazoo, USA) for prostaglandin standards, Mrs J. D. Brunt for assay work, and Professor A. C. Turnbull and Dr A. Anderson for advice.

This work was supported in part by an MRC programme grant awarded to Professor A. C. Turnbull, and A.R.W was supported by the National Foundation, The March of Dimes, USA. M.D.M holds the Staines Medical Research Fellowship at Exeter College, Oxford.

Maturation of caffeine elimination in infancy

JACOB V. ARANDA, JUDITH M. COLLINGE, RAEZELLE ZINMAN, AND GORDON WATTERS

Departments of Newborn Medicine and Neurology, McGill University-Montreal Children's Hospital Research Institute, and Roche Developmental Pharmacology Unit, Department of Pharmacology and Therapeutics, McGill University, Montreal

SUMMARY The developmental changes in caffeine elimination were studied in 7 infants aged between 2½ weeks and 6 months. Adult plasma clearance rate of caffeine was achieved at 3 to 4½ months of age. Plasma half-life and elimination rate reached adult levels after 3 to 4½ months and seemed to exceed adult capacity thereafter. No significant changes in apparent volume of distribution were noted. Our data provide some indication of the age in infancy when the low rates of caffeine elimination in the neonate increase to the adult rate.

Caffeine (1, 3, 7, trimethylxanthine) is a central nervous system stimulant with many pharmacological activities. It is an ubiquitous compound found in many beverages, food, and medicines. Substantial exposure of the developing human organism to this compound occurs via placental transfer (Parsons *et al.*, 1976; Bory *et al.*, 1979) postnatally via breast milk (Horning, 1977) or intentionally in the treatment of neonatal apnoea (Aranda *et al.*, 1977a). The elimination of this drug in the human neonate is exceedingly slow, far more so than is the case with other drugs (Aranda *et al.*, 1977b, 1979). The plasma half-life and clearance in the premature neonate ranges from 40 to 230 hours (mean = 100) and 2·5 to 16·8 ml/kg per h (mean = 8·9), respectively. This implies that the breast-fed newborn and young infant with a significant daily intake of caffeine via maternal breast milk could potentially accumulate caffeine in the body. However, beyond the neonatal period, there are no data on the elimination of caffeine, and the present study therefore attempts to define how caffeine elimination changes in early infancy. The investigative use of caffeine for the prevention of 'cot death' has afforded the opportunity to perform these studies.

Materials and methods

A total of 10 doses of caffeine citrate, 8 as single IV infusions and 2 as single oral doses, were given to 7 infants whose ages ranged from 2½ weeks to 6 months. Five infants were admitted for investigation of 'near-miss' sudden infant death syndrome. An additional 2 sick infants with severe apnoea were also included. One 3-month-old infant had complex congenital heart disease, congestive heart failure, and apnoea, and was respirator dependent. One 6-month-old infant had persistent apnoea with Arnold-Chiari malformation. One infant with 'near-miss' sudden infant death syndrome was studied at ages 2½, 5, and 10 weeks. Another infant was also studied sequentially at ages 4½ and 5 months. Informed consent was obtained from the parents. This study protocol was approved by the Scientific Review Committee and the Ethics Committee of the Montreal Children's Hospital.

After the IV or oral administration of caffeine citrate (10 mg/kg of caffeine base), multiple capillary blood samples were obtained at varying intervals from 30 minutes to 72 hours. Using a plasma volume of 10 μl, caffeine was measured by radioimmunoassay as described by Cook *et al.* (1976). Metabolite cross-reactivity is negligible as previously determined at this laboratory.

Data were analysed using a one-compartment model. This analysis has been shown to be applicable in the pharmacokinetic disposition of caffeine in the newborn (Aranda *et al*, 1979), and of theophylline in the newborn (Aranda *et al.*, 1976) and young infant (Loughnan *et al.*, 1976). The plasma concentrations of caffeine were plotted semilogarithmically and the slope of the curve (elimination rate constant or K_{el}) was calculated with the use of log-linear least-square regression analysis. Apparent volume

GORDON WATTERS, professor of paediatrics and neurology

of distribution (AV_d) was calculated as dose over the plasma concentration extrapolated to time zero (C_p^o). Plasma half-life was derived from $0{\cdot}693/K_{el}$ and the clearance rate as the product of K_{el} and AV_d. In the 2 infants who received caffeine orally, analysis assumed complete bioavailability of the drug.

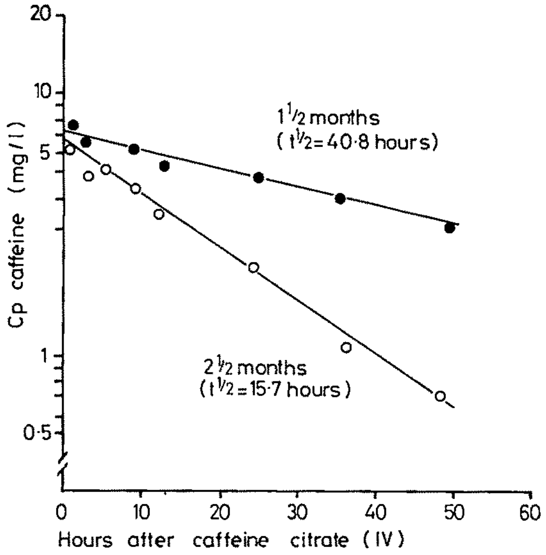

Figure *Plasma disappearance curve of intravenously administered caffeine in the same infant at ages 1½ and 2½ months. Caffeine citrate, 10 mg/kg and 5 mg/kg of active caffeine base, were infused at ages 1½ and 2½ months, respectively. Plasma disappearance curve of caffeine in this infant at an earlier age (2½ weeks) was similar to the value obtained at age 1½ months (t½ — 40·8 hours).*

Results

The Figure shows the sequential changes in the plasma disappearance curve of caffeine in a young infant with increasing postnatal age. The Table shows the pharmacokinetic profile of caffeine as a function of age. Comparative data for the newborn and adults from the same laboratory were included. There was little change in the mean AV_d over the age period studied. Plasma half-life shortened by 1–2½ months of age and attained adult t½ by between 4 and 6 months. Plasma clearance of caffeine progressively increased and achieved comparable adult capacity by 3 to 4½ months and exceeded adult capacity by 5 to 6 months of age. Change in clearance was mainly a function of an increased elimination rate constant. There was a wide variability in the elimination rate and clearance of caffeine in the newborn and young infant. This wide variability was also observed in adults (Table).

Discussion

The observation that drugs are eliminated more slowly by neonates than by adults is no longer surprising but the magnitude and duration of the deficit in the case of caffeine exceeds expectations based on the behaviour of other drugs—such as theophylline (Aranda *et al*,. 1976), phenytoin (Loughnan *et al.*, 1977; Painter *et al.*, 1978), and phenobarbitone (Jalling, 1975; Painter *et al.*, 1978). Both phenytoin and phenobarbitone exhibit 2-to 6-fold prolongation in the plasma half-life relative to the adult (Neims *et al.*, 1976) and the adult level of elimination is achieved within the first month of postnatal life (Neims *et al.*, 1976). In contrast, the plasma half-life

of caffeine represents a 17-fold prolongation relative to the adult, and the adult capacity to eliminate the drug is achieved much later (3–4½ months).

One biochemical basis for this finding could be a decreased oxidative metabolism of caffeine by the newborn and young infant (Aranda *et al.*, 1974; Neims *et al.*, 1976). In adults, less than 2% of a caffeine dose is eliminated unchanged in urine, the remainder being metabolised in the liver to a series of partially demethylated xanthines and methyl uric acids (Cornish and Christman, 1957; Burg, 1975). In contrast, Horning *et al.* (1975) found that transplacentally acquired caffeine was largely excreted unchanged in comparison with its demethylated metabolites in the urine of 1- to 3-day-old neonates. This was confirmed by Aldridge *et al.* (1979), who found that unchanged caffeine comprised more than 85% of the methylated xanthines and methyl uric acids in the urine of infants less than one month of age. These observations indicate a distinct neonatal deficiency in the capacity to metabolise caffeine, and this deficit persists for many weeks since caffeine remained the predominant component in the urine for at least 3 months postnatally. It is intriguing to relate that the adult plasma clearance rate is achieved at 3–4½ months (Table) coincident with the increased capability to produce demethylated metabolites (Aldridge *et al.*, 1979).

The oxidative metabolism of drugs via the cytochrome P-450 mono-oxygenase system is deficient in the human neonate (Aranda *et al.*, 1974; Neims *et al.*, 1976). The relative deficiency with regard to methylxanthine metabolism is greater than seen with other drugs. One subcellular explanation for this difference relates to the existence of multiple forms of cytochrome P-450, each with distinctive substrate specificity and maturational sequence (Thomas *et al.*, 1976; Manchester and Neims, 1977). Caffeine is a good substrate for those form(s) of cytochrome P-450 preferentially induced by polycyclic aromatic hydrocarbons in rats (Welch *et al.*, 1977) and in man. This form of cytochrome P-450 with specific activity for caffeine is probably deficient in the fetus and newborn as suggested by negligible aryl hydrocarbon hydroxylase activity (about 2% of adult value) in the human fetal liver compared with other oxidative enzymes of the mono-oxygenase complex that preferentially metabolise drugs like phenytoin or phenobarbitone (25–50% of adult value) (Pelkonen *et al.*, 1973; Neims *et al.*, 1976).

Phenobarbitone and phenytoin, both known enzyme inducers, were used in one infant (Table) with the highest clearance rate. The possibility that the elimination of caffeine in this infant could have been induced by these drugs exists, but available data suggest that phenobarbitone and phenytoin have little effect on methylxanthine disposition (Greene *et al.*, 1977; Piafsky *et al.*, 1977; Ogilvie, 1978).

The lack of correlation between indices of maturity (gestational age, postnatal age, birthweight) and the kinetic variables (AV_d, $t\frac{1}{2}$, K_{el}, and clearance) during the first 4 weeks of life (Aranda *et al.*, 1979) suggest that elimination does not change during the first few weeks of postnatal life. Shortening of the plasma $t\frac{1}{2}$ starts to occur after the neonatal period and appears to reach adult $t\frac{1}{2}$ by 5–6 months, perhaps to be exceeded thereafter. A much greater clearance rate of drugs in infants after one year of age has been documented with other drugs—such as digoxin (Morselli *et al.*, 1975; Wettrell, 1977; Wettrell and Anderson, 1977) and theophylline (Loughnan *et al.*, 1976; Ogilvie, 1978). Caffeine appears to behave similarly, based on the observations of a 3-fold increase in the mean caffeine clearance rate in the 5- to 6-month-old infant (Table). The fundamental basis for this accelerated clearance rate in older infants compared with adults remains unknown. Similarly, the duration of this accelerated elimination is also not known. The oldest infant studied here was 6 months and ethical consideration has precluded extension of this study to older normal healthy infants.

In summary, our data show that caffeine elimination, unlike that of other drugs, is exceedingly slow in the neonate with tardy maturation to the adult level.

We thank Dr Allen H. Neims in whose laboratory some of the caffeine assays were done, and Rena Jain for technical assistance. This work was supported by grants from the Medical Research Councils of Quebec and Canada.

Effect of puberty on rates of bone growth and mineralisation

With observations in male delayed puberty

S. KRABBE, C. CHRISTIANSEN, P. RØDBRO, AND I. TRANSBØL

Children's Hospital, Fuglebakken, Copenhagen, Department of Clinical Chemistry, Glostrup Hospital, Department of Clinical Physiology, Aalborg Sygehus (Syd), and Division of Endocrinology, Department of Internal Medicine, Hvidovre Hospital, Denmark

SUMMARY The bone mineral content (BMC) and body height were measured in 301 normal children and adolescents aged 7–20 years, and in 8 boys with constitutional delayed puberty aged 14–17 years. Serum testosterone was measured in the last group as well as in a subpopulation of the normal children and adolescents. The growth spurt, which coincided with a steep increase of serum testosterone in boys, indicated a great change in skeletal growth and mineralisation in both sexes. After the growth spurt, linear growth slowed down considerably while bone mineralisation rose steeply. When low levels of serum testosterone were maintained, as in delayed puberty, these combined changes of skeletal growth and mineralisation did not occur. It is suggested that gonadal hormones are the true initiators of the short-lived growth spurt as well as of prolonged acceleration of bone mineralisation.

Measurement of bone mineral content (BMC) by photon absorptiometry is a precise, reliable, and easy method for assessing skeletal status (Christiansen *et al.*, 1975a). BMC varies with age and sex and the biological variation is greatest during puberty (Christiansen *et al.*, 1975b). In this period of outstanding growth the chronological age may be a poor indicator of physical development, as there is a wide range of growth and sexual maturation in individuals of the same age (Marshall and Tanner, 1970). In boys, serum levels of testosterone correlate well with the pubertal stage (Knorr *et al.*, 1974), and this is a better measure of physical development than chronological age during adolescence. Determinations of serum testosterone and of various indicators of bone status have been used to assess the physical development in the adolescent, but comparisons between BMC and serum testosterone have not been reported.

In order to evaluate skeletal growth and mineralisation in relation to age and development we examined BMC, serum testosterone, and body height in normal boys during childhood and adolescence, and in boys with constitutional delayed puberty.

Patients and methods

Normal children and adolescents. A total of 301 normal children and adolescents aged between 7 and 20 years participated in the study. They were randomly selected from pupils at two schools in a surburban area. Pupils below 18 years obtained written consent from their parents. All were in good health without symptoms of gastrointestinal or renal diseases. None took contraceptive pills or any other type of drug. Data on sex, age, and height are given in Figs 1 and 2.

Boys with delayed puberty. Eight boys, referred to the clinic for delayed growth or delayed pubertal development, or both, were chosen. The diagnosis was constitutional or familial delayed puberty

(Wilkins, 1965) without signs of other endocrine disease. Based on data on pubertal changes in normal boys (Marshall and Tanner, 1970) the retardation in pubertal development was at least 2 SDs in 6 boys and between 1 and 2 SDs in 2 boys. Testicular size was within the pubertal range in all boys.

Methods

BMC was determined by direct photon absorptiometry (Christiansen *et al.*, 1975a). The forearm was fixed in a plexiglass container filled with distilled water. A source of radiation (25 mCi^{125}I) and a detector were placed on each side of the forearm to be examined. As these moved across the arm the transmission of photons through the bones decreased depending on the bone mineral content. Because the absorption in plexiglass, distilled water, and soft tissue is almost identical, the measurement was independent of the amount of soft tissue. The scanner started distally on the forearm, moving 4 mm proximally between each scan. The first scan was defined as that demonstrating a distance between radius and ulna of at least 2 mm. The bone mineral content was expressed in arbitrary units as a mean of 6 scans on each forearm. The coefficient of variation in normal subjects is about 2%.

From the 156 normal boys, a subgroup of 103 was randomly selected for determination of serum levels of testosterone. Serum testosterone was measured by radioimmunoassay including a modification of thin-layer chromatography (Pirke, 1973).

Results

Normal children and adolescents. Figs 1 and 2 give the heights and BMC values in boys and girls divided into one-year age groups. Before the growth spurt—between ages 11 and 12 years in girls, and 2 years later in boys—the mean height and BMC increments each year were similar in boys and girls. The respective height increments were 4·5 and 4·7 cm per year, while BMC increased very slowly, 0·14 and 0·09 units per year. After the growth spurt linear growth procedeed slowly at average rates of 1·5 and 0·5 cm per year respectively, while there was a large increase in BMC in both sexes. During this phase of development the BMC increments averaged 2·23 units per year in boys and 1·13 units per year in girls (Figs 1 and 2).

Fig. 3 shows the association between serum testosterone and age in the boys. A sharp increase was found at ages 13 and 14 years, simultaneous with the growth spurt (Fig. 1).

Boys with delayed puberty. For their chronological age of 15·9 ± 0·9 years these boys were small, 155·0 ± 4·8 cm, and had very low BMC values averaging 27·2 ± 4·0 units, corresponding to 66%

of age-matched normal boys. Their average level of serum testosterone was also low, 2·8 ± 4·1 nmol/l (0·80 ± 1·18 ng/ml) (Fig. 3). All these values are given as mean ± 1 SD.

Discussion

The onset of the adolescent growth spurt is an important event in skeletal development. In addition to the rather short-lived spurt of growth, it indicates the start of a much more prolonged acceleration of bone mineralisation in both sexes. The timing within the same year of a steep increase of the serum testosterone levels in boys (Fig. 3) with the growth and mineralisation spurt suggests an important role for testosterone in the initiation of both processes and probably in the maintenance over several years of the accelerated bone mineralisation. This view is supported by our observations in boys with delayed puberty: the maintenance of low levels of serum testosterone postpones the onset of the growth and mineralisation spurt. As the peak height increment and the increase in BMC in girls occur at ages 11 to 12 years, when rising levels of plasma oestrone and oestradiol are being observed (Gupta, 1975), it also seems reasonable to assume that rising levels of these hormones serve as the initiator of both spurts in girls. Gonadal hormones may exert their effects on mineralisation through a complex of mechanisms. Firstly, these hormones may have a direct inhibiting effect on bone resorption, although data from tissue culture studies are conflicting (Atkins *et al.*, 1972; Caputo *et al.*, 1976). Secondly, gonadal hormones are potent stimulators of the production of the biologically active vitamin D3 metabolite, 1,25 $(OH)_2$ D_3, in birds (Tanaka *et al.*, 1976), and have also been found to increase plasma calcitonin levels in normal man (Hillyard *et al.*, 1978). Thirdly, androgens may also enhance the skeletal sensitivity to calcitonin, as shown in the rat (Ogata *et al.*, 1970).

The results in the boys with delayed puberty show the importance of using proper reference materials especially in adolescents. If the BMC values are compared with those of age-matched controls, as is done conventionally for the purpose of calcium metabolic investigation, a diagnosis of severe osteopenia would be made. Therefore we suggest that BMC measurements in pubertal boys should be evaluated from testosterone levels or physical development, rather than from chronological age.

Figs 1 and 2 show that the greatest dissociation between skeletal growth and mineralisation takes place during the last years ahead of the growth and mineralisation spurt. This phenomenon may in fact explain the peak incidence of forearm fractures observed in children of 10–14 years of age (Alffram and Bauer, 1962)

Lymphocyte changes in β-thalassaemia major

S. MUSUMECI, G. SCHILIRO, M. A. ROMEO, A. SCIOTTO, A. ROSALBA, AND G. PIZZARELLI

Department of Paediatrics, University of Catania, Italy

SUMMARY Lymphocyte subpopulations were studied in 20 hypertransfused patients with β-thalassaemia major, some of whom had been splenectomised. B-lymphocytes were normal but T-lymphocytes were decreased in all patients. The T-cell count was lower in the splenectomised patients than in the nonsplenectomised ones. In the former, the active rosette-forming lymphocytes were also diminished, but the difference was not significant. In all patients the percentage of null cells was greater and the activity of K-cells increased compared with controls.

Many patients with β-thalassaemia develop chronic liver disease (Ellis *et al.*, 1954; Panizon and Vullo, 1957; Beltrami and Nenci, 1969; Masera and Jean, 1973). This complication has been attributed to hepatitis virus infection in a liver already stressed by the iron overload (Masera and Jean, 1973; Masera *et al.*, 1976). As chronic hepatitis may be related to an immunological dysfunction, we studied the lymphocyte subpopulation in a group of patients with thalassaemia major. A decreased proportion of T-cells associated with greater K-cell activity is reported.

Methods

20 patients, aged between 3 and 22 years, with thalassaemia major were studied. Eight had undergone splenectomy. Each was regularly transfused with packed red cells every 20–30 days in order to maintain Hb>9 g/dl. 12 normal subjects, aged between 3 and 12 years, served as controls. Serum transaminases were determined; Hb_sAg and Hb_sAb by the solid radioimmunoassay method (AUSRIA II and AUSAB); immunologlobulin levels and C3 and C4 components of serum complement by single radial immunodiffusion, using specific antisera (Kallestad). Purified lymphocytes were obtained by fractionation of heparinised blood on a Ficoll-Hypaque density gradient (MSL Eurobio). In some experiments residual phagocytic cells were eliminated by incubating the cells with iron powder and removing the phagocytic ones with a magnet. T-lymphocytes were identified by sheep red cell rosetting (SRCR) technique (Jondal *et al.*, 1972) and active rosette-forming lymphocytes were identified by the method of Wybran *et al.* (1972), modified by Horowitz *et al.* (1975). B-lymphocytes were identified by the presence of fluorescence on their surfaces when treated with antiwhole immunoglobulin conjugate (Kappel Laboratories), using the technique of Permis *et al.*, 1970. K-cell activity was measured by ^{51}Cr-labelled chicken red blood cell (CRBC) technique. Antibodies against chicken red cells were obtained in rabbits by injecting them with 1 ml 10% CRBC suspension twice weekly for 3 weeks. For the assay, CRBC (0·2 ml) were labelled with 100 μCi of ^{51}Cr sodium chromate for 30 min at 37°C. After incubation, the red cells were washed 3 times with RPMI 1640 and diluted to a concentration of $2{\cdot}5 \times 10^6$/ml. Then 0·1 ml of the lymphocytes at a concentration of $5{\cdot}0 \times 10^6$/ml was placed in a plastic tube containing 0·5 ml inactivated antibody at a dilution of 1:1000, 0·2 ml ^{51}Cr-labelled red cells, and 1·7 ml tissue culture medium. All the dilutions were made in RPMI 1640, supplemented with 10% fetal calf serum previously absorbed with CRBC. Control incubations were carried out in the absence of antibodies or lymphocytes, and a second control tube containing labelled red cells and distilled water was included in the experiment. After incubation overnight at 37°C, the tubes were gently centrifuged, the supernatant collected, and radioactivity of the supernatant measured.

Cytotoxicity was evaluated according to the formula:

Department of Paediatrics, University of Catania, Italy
S. MUSUMECI, associate professor
G. SCHILIRO, associate professor
M. A. ROMEO, assistant professor
A. SCIOTTO, assistant professor
A. ROSALBA, research fellow
G. PIZZARELLI, assistant professor

$$\frac{(^{51}\text{Cr sample tube})-(^{51}\text{Cr control tube})}{(^{51}\text{Cr distilled water})-(^{51}\text{Cr control tube})}\times 100$$

The spontaneous release of ^{51}Cr was always <10% in the control tube.

Results

The serological data for 20 hypertransfused patients are listed in Table 1. An increase in serum transaminases was observed in both groups, particularly in the splenectomised patients. IgA and IgG immunoglobulins were also increased in the thalassaemic patients, again particularly in the splenectomised ones. C3 and C4 in thalassaemic patients were normal, but C3 was slightly low in splenectomised patients. The Hb_sAg and Hb_sAb tests gave one Hb_sAg positive and 11 Hb_sAb positive, the remaining 8 patients had negative results. Eight patients developed a typical icteric hepatitis B. B- and T-lymphocyte assay and K-cell activity in the thalassaemic patients and controls are shown in Table 2 and the Figure. Regularly transfused patients had normal B-lymphocytes but fewer T-lymphocytes than controls. The T-cell count was lower in the splenectomised than the nonsplenectomised patients (P<0·005). The active rosette-forming lymphocytes were also diminished, but this difference was not significant.

*RF = Rosette-forming.

The percentage of null cells was significantly higher in the thalassaemic patients compared with controls, but the splenectomised did not differ from nonsplenectomised patients in this respect.

The activity of K-cells in the 20 hypertransfused patients was increased ($P<0\cdot0025$) compared with controls, but there was no difference between splenectomised and nonsplenectomised patients ($P<0\cdot25$). This increased K-cell activity was unaffected when phagocytes were removed with a magnet so that the greater activity did not appear to be caused by contamination with monocytes and polymorphs.

Discussion

Our study shows that a decrease of T-lymphocytes takes place in patients with β-thalassaemia major. This decrease is also reflected in the number of active rosette-forming lymphocytes. Wyler (1976) observed lower T-cell counts in children with splenomegaly due to malaria; he suggested that the T-cell lymphopenia was due to selective sequestration of T-lymphocytes in the spleen. However, our splenectomised patients had a lower mean T-cell count than nonsplenectomised ones. These results seem to exclude the spleen from a role in the depletion of T-lymphocytes. As our results give no evidence that the presence of a serum factor interferes with rosette formation, the mechanism of T-lymphocyte depletion in β-thalassaemia remains unknown.

The selective depletion of T-lymphocytes in β-thalassaemia seems to be unassociated with impairment of cell-mediated immunity (Kanakoudi-Tsakalidis *et al.*, 1977). It could be due to a depletion of particular T-cells, perhaps suppressor T-cells. Such a depletion of suppressor T-cells may contribute to the increased production of immunoglobulin observed in hypertransfused patients (a normal percentage of B-circulating lymphocytes was noted).

Casali *et al.* (1978) observed an increase in circulating soluble immunocomplexes in thalassaemics treated with multiple transfusions, related to the age of the patient; complement levels were also decreased. This increase of immunocomplexes seems to be a consequence of the development of chronic hepatitis due to HB virus or to iron overload, or both (Masera and Jean, 1973; Masera *et al.*, 1976). The immunocomplexes in β-thalassaemia could also occur through the isoantigen antibodies complexes due to blood transfusion (Pearson and O'Brien, 1975). Such immunocomplexes may stimulate K-cell activity, the greater number of null cells being then due to the increased number of K-cells.

It is not known whether the increased activity of K-cells is due to an increase in cytotoxic activity of individual cells or to an increase in cell number. Increased K-cell activity has been observed only in hypertransfused patients and is directly related to the age of the patient. Whether or not the patients had been splenectomised seemed to be immaterial, despite the fact that the splenectomised patients were significantly older than the nonsplenectomised ones. Increase of K-antibody-dependent cells was observed in chronic active hepatitis by Cochrane *et al.* (1976) and also in many acute and chronic liver diseases of infancy (Smith *et al.*, 1977). The presence of increased K-cell activity in β-thalassaemia suggests that these cells may play a key role in the cirrhosis affecting thalassaemic children.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onwards all manuscripts submitted should accord with the new style.

Concentration of zinc in the hair of schoolchildren

NICOLETTA HEINERSDORFF AND T. G. TAYLOR

Department of Nutrition, School of Biochemical and Physiological Sciences, University of Southampton

SUMMARY The concentration of zinc in the hair of 219 schoolchildren aged between 10 and 11 years was measured and related to height, weight, estimates of consumption of zinc-rich foods, number of children living at home, and rank in family. None of the correlation coefficients between hair zinc and the other variables was significant. Mean concentration of zinc was higher ($P<0\cdot001$) in the girls (146 µg/g; 2·23 µmol/g) than in the boys (118 µg/g; 1·81 µmol/g). Eight children (3·7% of the total) had <75 µg/g (<1·15 µmol/g) zinc in their hair but only one of them was below the 10th centile for height or weight—a girl with coeliac disease.

A condition of zinc deficiency associated with dwarfism and hypogonadism was first observed in young adult men in Iran (Prasad *et al.*, 1961), and Egypt (Prasad *et al.*, 1963), and it was later reported in 2 young Iranian women (Ronaghy and Halsted, 1975). Zinc deficiency has also been identified in adolescent boys in the Middle East (Ronaghy *et al.*, 1974), and in boys and girls in the USA (Hambidge *et al.*, 1972), but no reports have been published of zinc deficiency in any normal British population.

Zinc deficiency in children before the age of puberty is characterised by retarded growth, poor appetite, and loss of taste acuity (hypogeusia). Hambidge *et al.* (1972) considered that a hair zinc concentration of <70 µg/g (<1·07 µmol/g) represented marginal zinc deficiency, and in a group of 132 children aged between 4 and 16 years in Denver, Colorado, 10 had hair zinc concentrations lower than this. Eight of these children had heights at or below the 10th centile on the Iowa growth charts and 5 responded to treatment with zinc.

Methods

Since the concentration of zinc in hair is often used as an index of zinc-status, we undertook a survey of the zinc content of the hair of 10- to 11-year-old children to see whether or not a deficiency of zinc could be detected. The children came from four different schools in the Southampton area. All the children (403) in this age group were invited to participate in the survey, and 219 agreed. With the exception of 2 Negro children and one Indian child, all were white, The heights and weights of the 219 children were measured, and 157 of them returned the diet sheet and simple questionnaire which they had been asked to complete. The questionnaire contained questions about the date of birth of the child, heights and occupation of the parents, the rank of the child in the family, and whether or not he or she had school meals or was on a special diet (for example, for reasons of health or religion).

Rough estimates of zinc intake were made by classifying foods into 5 categories according to zinc content, class 1 foods (for example fruit, leafy vegetables, butter) containing the smallest amounts of zinc and class 5 (for example, lamb, beef) containing the greatest, and calculating the weight for each category of food eaten.

Samples of hair (10–20 mm in length and weighing about 500 mg) were taken close to the skin from the same region of the nape of the neck for each child; these were then cut into lengths of 1–2 mm with scissors. After exhaustive washing with acetone, detergent solution (sodium lauryl sulphate, 100 g/l), and distilled water in sequence, followed by a final rinse in acetone, the hair samples were air dried between filter paper. Duplicate samples of approximately 100 mg were digested in 2 ml concentrated nitric acid of a special grade, low in trace elements at 85°C for 2 hours in a stoppered tube. After cooling, the digests were made up to 25 ml with glass-distilled water and analysed for zinc by atomic absorption spectrophotometry. Analysis of 13 replicate samples from the hair of one individual gave values with a coefficient of variation of 6%.

Results

Correlation coefficients were calculated for each sex between individual hair zinc values and height, weight, number of children living at home, rank in family, and consumption of the different categories of zinc-containing food, and none of these coefficients was statistically significant. The correlation coefficients between number of children living at home and height (−0·37) and weight (−0·41) were, however, significant ($P<0{\cdot}01$) as were the correlations between rank in family and height (−0·21), and maternal and child's height (+0·23).

The mean hair zinc concentration was higher in girls than boys ($P<0{\cdot}001$) (Table 1). This large sex difference has not been reported previously in children, probably because no other studies have been carried out with such large numbers of children over such a narrow age range. The distribution of hair zinc values was normal (Table 2). The mean values are similar to those reported by Klevay (1970) for this age group in Panama, but are somewhat lower than the values observed by Hambidge *et al.* (1972) for American children. Eight children, 6 boys and 2 girls, had <75 µg/g zinc in their hair but only one of these children was below the 10th centile for height or weight—a girl with coeliac disease.

14 children were found with heights at or below the 10th centile and 19 had weights below this centile but, apart from the girl with coeliac disease, none had hair zinc <90 µg/g (<1·38 µmol/g). There was thus no evidence that short stature and low weight were associated with zinc deficiency, or indeed that the deficiency of zinc suggested by low hair zinc was sufficiently serious to depress growth. All the diet sheets available for the normal children in these subsamples suggested that their diets were adequate in both quality and quantity, but the records were not sufficiently detailed to permit any accurate calculations of actual zinc intakes to be made.

Table 1 *Concentration of zinc in the hair of 10- to 11-year-old schoolchildren*

		Concentration (µg/g)		
		Mean	*Range*	*SEM*
Boys	(n = 92)	118	30–189	3·1
Girls	(n = 127)	146*	70–235	2·8

Conversion: traditional units to SI—1 µg/g ≈ 0·0153 µmol/g
*Significantly greater than the mean for the boys ($P<0{\cdot}001$, Student's *t* test).

No assessment was made of the stage of sexual development of the children but it was clear from their heights and weights that whereas most of the girls had entered the adolescent growth spurt, only a few of the boys had done so. Only 6 of the 127 girls had reached the critical weight of 48 kg which Frisch and Revelle (1971) have related to the menarche. The range of hair zinc of these 6 girls was 90–200 µg/g (1·38–3·06 µmol/g), a mean of 139 ± 15·5 µg/g (SEM) (2·13 ± 0·24 µmol/g), indicating that this subgroup did not differ significantly from the whole population.

Discussion

There was no evidence of a serious deficiency of zinc in these 219 normal children, despite the fact that 3·7% of them had concentrations of zinc in their hair within the range commonly accepted as indicative of a marginal deficiency.

Requirements for zinc increase at puberty, particularly in boys, presumably associated with the high concentration of zinc present in the testes and accessory male sex glands (Mawson and Fisher, 1953), and a deficiency of this element appears to be more common in males than in females. In this context it is interesting to note that the mean hair zinc concentration was lower in the boys than the girls in this series, suggesting that boys may have smaller body reserves of zinc than girls to support the increased demands of puberty.

A similar sex difference in hair zinc concentration has recently been reported among New Zealand students aged between 18 and 27: in that study the mean hair zinc in the male subjects was 180 ± 3·9 (SEM) µg/g (2·75 ± 0·06 µmol/g) and in the females 195 ± 3·1 µg/g (2·83 ± 0·05 µmol/g) ($P<0{\cdot}01$) (McKenzie, 1979).

A major problem in using hair as a biopsy material for the assessment of trace element status is the danger of contamination by extraneous matter, particularly by cosmetics; whereas superficial 'dirt' is readily removed by efficient washing, lacquers and dyes may be impossible to remove completely by

Table 2 *Distribution of zinc concentrations in the hair of 10- to 11-year-old schoolchildren*

normal washing. We were certainly aware of these problems and renewed each portion of wash liquid until it remained absolutely clear and colourless, but no comparisons were made between the zinc content of unwashed samples and samples at different stages of the washing process. Although the possibility that the sex difference observed in hair zinc concentrations was due to the greater use of zinc-containing cosmetic preparations by the girls cannot be ruled out entirely, this explanation seems rather unlikely in view of the age of the children, particularly as our mean values were somewhat lower than those reported for American children. Furthermore, McKenzie (1978) showed that treatments such as dyeing, bleaching, and cold waving decrease the zinc concentration of hair. Nevertheless, in retrospect, we wish we had included a question on the use of hair preparations in our questionnaire.

Further studies should be carried out on the zinc status of older children and adolescents. In the Middle East, zinc deficiency is thought to be conditioned by the high phytate content of the staple food of the population, unleavened whole-wheat bread, and the zinc nutrition of the children of Asian immigrants in Britain, many of whom are vegetarians and whose diet includes chappatis made from flour rich in phytate, merits particular study.

We thank the staff, pupils, and parents of Newlands, Wimpson, and Aldermoor Middle Schools, Southampton, and of Abbotswood Primary School, Totton, for their help.

Short reports

Cerebrospinal fluid immunoglobulins in children

D. G. GILL AND MARY BRODY

Children's Hospital, Dublin

SUMMARY Cerebrospinal fluid (CSF) immunoglobulins were measured in 62 normal children, in 9 children with purulent meningitis, and in 10 children with presumptive viral meningitis. The mean values in normal children were IgA 0, IgM 0, and IgG 0·84 ± 1·4 mg/100 ml (± SD). The mean levels of all CSF immunoglobulins were raised in acute bacterial meningitis and were significantly greater than the levels found in viral meningitis. CSF IgM was 0·16 ± 0·5 mg/100 ml in viral meningitis compared with 2·64 ± 2·06 mg/100 ml in bacterial meningitis ($P<0·01$). However, these values overlapped to a considerable extent and, generally, measurement of CSF immunoglobulins did not enhance diagnostic accuracy in this group of children.

Smith *et al.* (1973) presented data on CSF immunoglobulins in meningitis in adults, and suggested that the levels of IgM might help to distinguish viral from bacterial meningitis.

Methods and material

CSF immunoglobulins were measured in 81 children aged between 0·1 and 10½ years. The indications for spinal tap were meningitis, suspected meningitis, convulsions, or (for therapeutic purposes) leukaemia. The 62 children designated as normal had WBC <10 × 10^6/l (<5 × 10^6/l in all except 4), and normal CSF protein and glucose relative to age. Most of the children were being evaluated for suspected meningitis or because they had had febrile convulsions. Nine children were considered to have bacterial meningitis, of which 3 proved to be due to *Haemophilus influenzae*, 3 to *Neisseria meningitidis*, 1 to *Staphylococcus albus*, and 2 showed no growth on culture. In 10 children meningitis was presumed to be viral in origin on the basis of leucocyte response, CSF protein and glucose levels, and clinical course. Specific viral cultures were not performed.

Lumbar puncture was performed as indicated on admission and the CSF analysed routinely in the laboratory. An unspun aliquot of the CSF was stored at 4°C before the immunoglobulins were estimated. CSF immunoglobulins were measured without knowledge of the child's clinical or routine CSF findings. Cerebrospinal fluid samples which were grossly blood-stained or which contained RBC >100 × 10^6/l were discarded.

CSF immunoglobulins concentrations were measured by the radial immunodiffusion method (Mancini *et al.*, 1965), using commercial L.C. Partigen plates and pooled human serum (Behring) as standard. 5 μl centrifuged, undiluted CSF was placed in the application wells and incubated for 72 hours at room temperature. Appropriate dilutions of standard in normal saline were also prepared. To intensify the precipitin ring the IgM and IgA plates were rinsed in phosphate-buffered saline for 24 hours, then covered with a 4% aqueous solution of tannin for 30 minutes and washed with distilled water. Standard curves were prepared from the square of the precipitin rings.

Results

Table 1 shows that IgA and IgM were not detected in

Table 1 *Clinical and CSF findings in 81 children (mean ± SD)*

	Normal CSF (n = 62)	*Viral meningitis (n = 10)*	*Bacterial meningitis (n = 9)*
Mean age (years)	2·4	5·1	1·5
(Range)	(0·1–10·0)	(0·7–10·5)	(0·3–4·5)
WBC (× 10^6/l)	1·95 ± 2·0	148·1 ± 91·5	2352·1 ± 2756·0
Polymorphs (%)	—	43·4 ± 29·3	70·6 ± 29·9
Lymphocytes (%)	—	56·6 ± 216	29·4 ±32·4
Protein (mg/100ml)	12·9 ± 9·6	31·0 ± 28·5	163± 120·3
Glucose (mg/100 ml)	59·7 ± 16·7	63·8 ± 15·4	15·1 ± 16·3
IgA mg/100 ml	0·0	0·0	1·89 ± 2·2
IgM mg/100 ml	0·0	0·16 ± 0·5	2·64 ± 2·06
IgG mg/100 ml	0·84 ± 1·4	4·19 ± 9·1	17·88 ± 6·21

Conversion: traditional units to SI—CSF proteins: 1 mg/100 ml ≈ 0·01 g/l, glucose: 1 mg/100 ml ≈ 0·0555 mmol/l.

the CSF of normal children, 69% of whom were aged under 3 years; IgG ranged from 0·1 to 3·6 mg/100 ml with a mean IgG level of 0·84 mg/100 ml. In the 10 children with viral meningitis, IgM was undetectable in 9 children and present in a concentration of 1·6 mg/100 ml in one child; IgM was undetectable in 2 children with bacterial meningitis, and in the remainder it ranged from 0·75 to 5·1 mg/100 ml (mean 2·64). IgG levels were raised in excess of 5 mg/100 ml in 7 of 9 children with bacterial meningitis. The mean levels of all CSF immunoglobulins, particularly IgG, were significantly higher in bacterial than in viral meningitis (Table 2).

Discussion

It is known that serum immunoglobulins are lower in children than in adults. At age 1–2 years serum IgG, IgM, and IgA are 66, 59, and 25% of respective adult values (Stiehm and Fudenberg, 1966). It is believed that CSF immunoglobulins are derived by diffusion from serum, although the lymphoid tissue may produce IgG (Lord *et al.*, 1973).

Table 2 *Significance in the differences (mean ± SD) in distribution of CSF substances in three groups of children using the Mann-Whitney U test*

CSF	*Normal v. viral*	*Normal v. bacterial*	*Viral v. bacterial*
Protein	$P<0·01$	$P<0·01$	$P<0·01$
Glucose	NS	$P<0·01$	$P<0·01$
IgA	NS	$P<0·01$	$P<0·05$
IgM	NS	$P<0·01$	$P<0·01$
IgG	$P<0·05$	$P<0·01$	$P<0·05$

In the present study a statistically significant difference in CSF IgG levels was shown between normal children and those with viral or bacterial meningitis, although the levels overlapped. High levels of CSF IgG (>5 mg/100 ml) were found in 7 children, and high levels of IgM (>3 mg/100 ml) in 5 of 9 children with bacterial meningitis.

Retrospectively, CSF immunoglobulins did not enhance the diagnostic accuracy of acute childhood meningitis as similar information could be gained from study of the total differential white cell count in combination with protein and glucose analyses (Table 1).

Treatment of a neonate with propionic acidaemia and severe hyperammonaemia by peritoneal dialysis

M. F. ROBERT, D. J. SCHULTZ, B. WOLF, W. D. COCHRAN, AND A. L. SCHWARTZ

Department of Medicine, Children's Hospital Medical Center, Boston, and Department of Human Genetics and Pediatrics, Yale University, New Haven, USA

SUMMARY A moribund newborn infant with propionic acidaemia and severe hyperammonaemia was successfully treated by peritoneal dialysis. The removal of ammonia and possibly additional toxic metabolites by peritoneal dialysis may be life-saving in newborn infants with propionic acidaemia or other hyperammonaemic syndromes.

Propionic acidaemia is a rare inborn error of metabolism which can be present in the neonatal period with persistent ketoacidosis and altered neurological status (Rosenberg, 1978). Survival of an infant thus affected depends on rapid diagnosis and immediate institution of measures to alleviate the chemical imbalances accompanying the disease. The usual treatment is to restrict the proteins while maintaining adequate calories and fluids to prevent the accumulation of harmful metabolites, but occasionally deterioration of the condition of the patient necessitates more drastic removal of these metabolites. We report a case of a neonate with propionic acidaemia who had extremely high blood ammonia concentrations with coma, but who survived after the rapid removal of ammonia by peritoneal dialysis.

Case report

A 3-kg baby girl, born at term after an uncomplicated pregnancy to a 27-year-old mother, was the only child of nonconsanguineous parents. She did well initially and was breast fed for the first days of life. Tachypnoea (>80/min) was noted on the second day of life (Figure) and hepatomegaly on the third, when the baby was transferred to Boston Children's Hospital Medical Center.

On admission (day 3), arterial blood–gases showed a metabolic acidosis with a compensatory respiratory alkalosis—pH 7·30, Po_2 110 mmHg (14·6 kPa), Pco_2 12 mmHg (1·6 kPa), total CO_2 6 mmol/l. White blood cell and platelet counts were normal. Chest *x*-ray was normal. Serum electrolytes were Na 144, K 4, and Cl 103 mmol/l, resulting in an anion gap of 39 mmol/l, indicating severe metabolic acidosis. The baby had protracted hypoglycaemia which required dextrose infusion, initially at 6 mg/kg per min, to maintain a blood glucose concentration of 100–200 mg/100 ml (5·5–11 mmol/l). When the dextrose infusion was stopped there was a fall in blood glucose within 30 minutes to 27–36 mg/100 ml (1·5–2·0 mmol/l), a level which persisted for more than 2 hours. Thereafter, dextrose infusion at 8 mg/kg per min was required to maintain normoglycaemia. Additional studies included a urine dinitrophenylhydrazine test which was positive for α-keto acids and urine, and plasma amino-acid profiles which were within normal limits. Plasma glycine was 432 mmol/l (normal, 120–560 mmol/l).

On day 4, the baby was flaccid and had sustained ankle clonus. There was no evidence of infection. Because of this change in her previously normal neurological status and the evidence of a metabolic disorder, blood ammonia was determined and was noted to be high at 150 µg/100 ml; 83 µmol/l (normal, less than 50 µg/100 ml; 28 µmol/l). On day 5, her blood ammonia level rose to 350 µg/100 ml (194 µmol/l). She became stuporous in spite of vigorous hydration and adequate caloric administration with dextrose. Attempts to perform an exchange transfusion were unsuccessful.

Therefore, peritoneal dialysis was started, cycling 150 ml each hour with an intra-abdominal dwell time of 30 minutes (dialysis solution per litre: Na 132, Cl 102, K 3·5, Ca 10, Mg 1·5, HCO_3 25 mmol/l, dextrose 15 g, pH 6·8). During the 8th cycle, the respiration arrested and was subsequently maintained by assisted ventilation for approximately 27 hours. At the time of her respiratory arrest, the baby was in coma, with fixed dilated pupils, no spontaneous respirations, and absent reflexes. Blood ammonia shortly after the arrest was 1350 µg/100 ml (748 µmol/l). EEG was consistent with severe toxic encephalopathy.

Despite the baby's condition, dialysis was continued. Subsequent measurements of blood ammonia before and after a dialysis cycle showed a decrease of approximately 100 µg/100 ml (55 µmol/l) during the cycle. At 15 hours, she was no longer acidotic. She then began to move spontaneously, and there was gradual neurological improvement. After 30 dialysis cycles (late on day 6), ammonia level was 150 µg/100 ml (83 µmol/l) and dialysis was stopped. She breathed spontaneously and had reactive pupils. She was extubated on the morning of day 7.

On the 8th day, she was started on a low protein diet, 100 kcal/kg (0·5 g/kg per day) with 50% of her calories as even short-chain triglycerides. Results of gas–liquid chromatography and mass spectrometry* of the urine showed the presence of 3-hydroxypropionic acid, methylcitrate, tiglylglycine, and

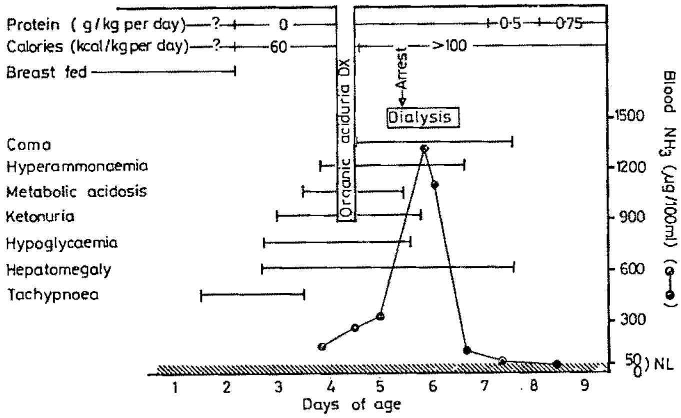

Figure *Course of patient with propionic acidaemia. Clinical events are noted on the right side and nutritional ones across the top. Blood ammonia concentrations are shown on the left ordinate with the normal range shaded. Age of the patient in days is given along the abscissa.*

propionylglycine, findings appropriate to the diagnosis of propionic acidaemia. She was therefore empirically started on 5 mg per day biotin orally, which was stopped when her defect was clearly defined by enzyme studies to be nonresponsive to biotin. She became increasingly alert, and was discharged from the hospital on day 12. Her daily diet consisted of 0·95—1·0 g protein/kg and 120 kcal/kg.

Since discharge, she has had several viral illnesses with associated metabolic acidosis, ketonuria, and a peak blood ammonia of 170 μg/100 ml (94 μmol/l); these have required parenteral treatment with fluids and a short time in hospital. Otherwise, she has remained in good metabolic control and has gained weight, being 6·6 kg at 15 months. Unfortunately, she developed an athetoid disorder during her second viral illness and her developmental milestones are delayed.

Fibroblast and leucocyte enzyme analysis

Propionyl CoA carboxylase (PCC) and β-methylcrotonyl CoA carboxylase (β-MCC) activities were measured in isolated peripheral leucocyte extracts and in skin fibroblast cultures established from the patient and her parents as previously described (Wolf and Rosenberg, 1978). As shown in the Table, the patient has deficient propionyl CoA carboxylase activity both in her fibroblast and leucocyte extracts. PCC activities in fibroblast and leucocyte extracts from both parents were intermediate between deficient and control values, whereas β-MCC activities in fibroblast extracts from the patient and her parents were normal. The patient's PCC was not stimulated by incubating her fibroblast cultures in medium containing 10 mg/ml biotin for 4 days. Fibroblasts from the patient were assigned to the A complementation group (Gravel *et al.*, 1977).

Discussion

The importance of rapid diagnosis of inborn errors of metabolism cannot be overemphasised. Our patient was 4 days old and semicomatose when hyperammonaemia was first noted. Persistent metabolic acidosis, ketonuria, and progressive deterioration in neurological status were all clues that the patient had a metabolic disorder. Tachypnoea, which developed during the period of breast-milk feeding, and hyperammonaemia pointed towards protein intolerance.

The presence of propionate metabolites in the urine suggested propionic acidaemia, the result of deficient activity of the enzyme propionyl CoA carboxylase that normally catabolises propionate to methylmalonate. The absence of raised propionate itself in the urine is probably due to its being metabolised via minor pathways and its conjugation with glycine, which is usually raised in the plasma and urine of patients with propionic acidaemia. The normal value of glycine in our patient was unusual and misleading. However, previous cases of propionic acidaemia with intermittently normal concentrations of glycine have been reported (Wadlington *et al.*, 1975). Furthermore, although most patients with propionic acidaemia have normoglycaemia, occasionally a case may demonstrate slight hypoglycaemia (Rosenberg, 1978); our patient, however, exhibited severe hypoglycaemia. The mechanism causing decreased blood glucose is not known but may involve the inhibition of gluconeogenesis.

In addition to propionic acid and glycine, ammonia concentrations may be raised in the blood of patients with propionic acidaemia. Hyperammonaemia, as seen in urea cycle disorders, Reye's syndrome, or hepatic failure, and ketoacidosis, as seen in diabetes, most certainly contributed to our patient's comatose state. Propionate, which unfortunately was not measured in our patient, or its metabolites, may also have primary or secondary toxicity.

Instituting a low-protein diet, sufficient carbohydrates, and even-chain triglycerides is essential, and is usually sufficient to achieve a homeostatic metabolism in patients with propionic acidaemia (Brandt *et al.* 1974). Our patient's rapid and severe neurological deterioration required more drastic therapy, peritoneal dialysis, to remove the toxic agents, but the fact that dialysis for 30 hours was required to return the ammonia level to normal suggests that our patient continued to produce ammonia probably by catabolism of her own protein. We cannot, however, exclude the harmful effect of a respiratory arrest in increasing the blood ammonia concentration or the beneficial effect of assisted ventilation in reducing the blood ammonia concentration. Peritoneal dialysis was previously used by Russell *et al.* (1974) to remove propionate from a severely ill infant with propionic acidaemia, but the ammonia levels were not measured. Peritoneal diaylsis has been used unsuccessfully to treat the severe hyperammonaemia associated with a patient with ornithine transcarbamylase deficiency (Siegel and Brown, 1973). The peak level of ammonia recorded for our patient is the highest yet reported in a patient with propionic acidaemia. This case is presented as the first successful demonstration that peritoneal dialysis together with protein restriction, adequate hydration, and sufficient caloric intake can be life-saving in propionic acidaemia even after the affected newborn has become moribund.

Note added in proof. At age 20 months, the patient developed a viral gastroenteritis, severe metabolic acidosis, and died.

We thank Dr L. E. Rosenberg for help with this patient.

Transient infantile hyperthyrotropinaemia

Report of a case

KIYOSHI MIYAI, NOBUYUKI AMINO, KEIKO NISHI, TOMIKO FUJIE, KIYOMI NAKATANI, OSAMU NOSE, TOKUZO HARADA, HYAKUJI YABUUCHI, KEI DOI, TOSHIHIDE YAMAMOTO, RITSUKO SATAKE, TSUNEO TSURUHARA, AND TOSHIAKI OURA

SUMMARY A case of transient hyperthyrotropinaemia was found by mass screening for neonatal hypothyroidism using the paired TSH assay method. The patient was a baby boy born at term after a normal pregnancy who grew without any abnormal signs or symptoms. For the first 7 months after birth, his serum TSH was abnormally high while his total serum T4, T3, and free T4, T3 were within normal limits, except for slightly low free T4 level at 7 months. The raised serum TSH decreased spontaneously to within normal limits after he was 9 months old.

With the recent development of techniques for testing thyroid activity, some interesting neonatal cases of thyroid dysfunction have been found. One of the most important developments in this field has been the introduction of mass screening for neonatal hypothyroidism, and several mass screening programmes have been reported. We have developed a new 'paired TSH assay method' (Miyai *et al.*, 1978). We were able to screen 91 400 babies between November 1975 and September 1978, and found 9 cases of primary hypothyroidism. We also found a boy who had high TSH but normal levels of thyroid hormones in the serum for 7 months, but whose TSH level decreased spontaneously to within normal limits after 9 months. This syndrome, which apparently differs from the transient neonatal hypothyroidism reported by La Franchi *et al.* (1977) and Delange *et al.* (1978), is described.

Case report

A baby boy was born after a normal pregnancy of 42 weeks without any complications or medications. Delivery was induced by aspiration, but vital signs of the baby were normal and the Apgar score was 10. At birth he weighed 3470 g and was 51·5 cm long. He had none of the normal signs of congenital hypothyroidism—such as, respiratory distress, hypothermia, peripheral cyanosis, hypoactivity, poor feeding, abdominal distention, vomiting, oedema, or prolonged icterus. His 33-year-old mother had 2 other children; both were girls, one was aged 7 and the other 5 years. The serum thyroid stimulating hormone (TSH), total thyroxine (T4), and total 3, 5, 3′-triiodothyronine (T3) were determined by double antibody radioimmunoassay and free T4 and T3 were determined by equilibrium dialysis. These results in the parents and siblings were within normal limits. By our mass screening test for neonatal hypothyroidism, the TSH in the patient's dried blood specimen was estimated as about 50 μU/ml, which is higher than the cut off point, and so he was again examined at 2 months. He was a well nourished infant, with no signs or symptoms of congenital hypothyroidism such as a cold, dry, mottled skin, an enlarged tongue, a hoarse cry, constipation, or goitre. He had an umbilical hernia but this disappeared at 4 months. At 9 months, *x*-ray examinations showed that the bone age and sella turcica were normal. His height and weight increased normally to 77·5 cm and 10 kg at 15 months.

The results of thyroid function tests are summarised in the Table. From 1 to 7 months, the serum TSH levels of the patient were significantly higher than those of age-matched normal babies. On radioimmunoassay, serial dilutions of serum at 2 months gave a curve parallel to that for serial dilutions of standard TSH. The raised TSH decreased to the upper normal limits from 9 months, and the TSH response to an intravenous injection of thyrotropin releasing hormone (TRH) (10 μg/kg) was also normal at 9 months. The serum concentrations of total T4 and free T4 were within normal limits except for low levels of free T4 at 7 and 9 months. Total T3 and free T3 were within normal limits. Total reverse T3 (r-T3) concentrations were within normal limits. Thyroidal uptake of ^{131}I and the standard energy metabolic rate were normal after 9 months, and tests for antithyroid antibodies were negative.

Discussion

Up to 7 months of age, the serum TSH level of this patient was found to be high by radioimmunoassay. This high level was not caused by a nonspecific reaction in radioimmunoassay because values for serial dilutions of the serum gave a curve parallel to that obtained with serial dilutions of standard TSH. The biological activity of the raised TSH is unclear.

Even if total T4 is normal, the increased thyroxine-binding globulin may cause decrease in free T4, which is considered to be the physiologically active

form. In our patient, the free T4 level was normal or low when TSH was raised before 7 months of age, and was low or normal when TSH became normal after he was 9 months old. At 9 months the response of TSH to TRH was within normal limits although free T4 was low. This finding indicates that decrease in free T4 was unlikely to be the cause of the raised TSH. Another active thyroid hormone, T3, is also known to be low in some neonatal conditions (Cuestas *et al.*, 1976). Our patient, however, had normal levels of total T3 and free T3 and was clinically euthyroid.

Several syndromes of inappropriate secretion of TSH have been reported, including neoplastic production of TSH, low response of the pituitary or peripheral tissues, or both of these, to thyroid hormone, and abnormal stimulation of TSH (Gershengorn and Weintraub, 1975). Increased TSH in addition to raised thyroid hormones is a characteristic of these syndromes. It is unlikely that our patient with a 'normal' T4 level and 'transient' hyperthyrotropinaemia had any of these syndromes.

Similar transient hyperthyrotropinaemia in infants was reported by La Franchi *et al.* (1977), and Delange *et al.* (1978). The infants they described had low total T4 when TSH was raised, and they called this syndrome 'transient neonatal hypothyroidism'. Our patient, however, had a normal total serum T4 level. Furthermore, his hyperthyrotropinaemia lasted for 7 months whereas in their patients it lasted only 2–6 weeks. Four of 6 cases reported by Delange *et al.* (1978) were in premature babies, but our patient was born at term. Therefore, this case dose not seem to be a case of transient neonatal hypothyroidism.

Oddie *et al.* (1977) reported that the progressive decrease in serum TSH and the increase in serum T4/TSH ratio in infants of 35 to 45 weeks' gestation is compatible with a progressive increase in feedback sensitivity to suppression of TSH release by thyroid hormone. Probably in this case slight immaturity in the responsiveness of the pituitary gland or of the peripheral tisssue or thyroid gland, or both, resulted in transient hyperthyrotropinaemia which maintained normal levels of serum thyroid hormones.

For effective treatment of congenital hypothyroidism, administration of thyroid hormones should be started as soon as possible. But we recommend that no treatment should be given in patients with high TSH but normal thyroid hormone levels, such as our patient.

This work was supported in part by grants from the Ministry of Health and Welfare and the Ministry of Education of Japan. We are grateful to Dr K. Kawabata for permission to study his patient, to Mr M. Kawashima for his technical help, to Dr and Mrs A. Ichihara for their valuable advice in preparing the manuscript in English, and to Mrs T. Wada and Miss M. Kawai for their secretarial assistance.

British Paediatric Association

Proceedings of the Fifty-first Annual Meeting

The Annual Meeting of the British Paediatric Association was held at York from 27–31 March 1979. 410 members attended together with 3 Heinz Fellows, Observers from the Department of Health and Social Security, and the Scottish Home and Health Department, and 226 guests. The George Frederic Still Memorial Lecture was given by Prof. R. J. Haggerty (Harvard School of Public Health). Three speakers from developing countries gave lectures at a session on Deprivation organised to commemorate the International Year of the Child.

The Annual General Meeting of the British Paediatric Association was held on Thursday, 29 March 1979. The President, Prof. O. H. Wolff, was in the chair.

The minutes of the last meeting, which had been published in the *Archives of Disease in Childhood*, were received and approved.

ELECTION OF OFFICERS. The following were elected.

PRESIDENT:	Dr G. M. Komrower
HONORARY SECRETARY:	Dr D. R. Harvey
HONORARY ASSISTANT SECRETARY:	Dr C. H. Nourse

MEMBERS OF COUNCIL 1979–82: Dr D. P. Addy, Dr J. D. Andrew, Prof. F. Cockburn, Dr B. W. Lewis, Dr L. Rosenbloom, Dr H. B. Valman, Dr S. G. F. Wilson.

HONORARY MEMBERS: Prof. H. Ali Khan, Dr N. Kretchmer, Dr R. Whitehead.

MEMBERS: C. J. Bacon (Northallerton), S. E. Barnes (Salisbury), N. R. Belton (Edinburgh), J. W. T. Benson (Liverpool), D. Bentley (London), I. Blumenthal (Bradford), J. G. Bissenden (Birmingham), R. L. Broadhead (Manchester), D. S. K. Brookfield (Southampton), L. P. Carroll (Leicester), D. J. Carson (Craigavon), I. Chalmers (Oxford), P. Congdon (Leeds), K. D. Connolly (Ballinasloe), Jennifer M. Cowen (Liverpool), J. G. Davies (Birmingham), Blanche M. Dawson (Aberdeen), Ruth E. Day (Glasgow), B. Denham (Dublin), J. F. Dossetor (Glasgow), E. J. Eastham (Newcastle), D. R. Evans (Cardiff), P. J. Fleming (Bristol), Sally E. Flew (Hounslow), Patricia Franklyn (Bradford), Eva A. Frommer (London), D. C. Gordon-Nesbitt (Manchester), Elizabeth Griffin (Dublin), D. Hall (London), C. P. Hallett (Bury), Katherine A. Hallidie-Smith (London), O. J. Hanmer (Aberdeen), R. F. Harris (Wegberg), J. Z. Heckmatt (Leeds), G. M. A. Hendry (Edinburgh), Elaine M. Hicks (Belfast), Marion Hommers (Coventry), I. A. Hughes (Cardiff), J. C. Hyde (London), Susan J. Ilett (Sheffield), J. G. Jenkins (Belfast), R. F. Joanes (Stourbridge), R. Leanage (London), R. J. Levinsky (London), J. MacKinnon (London), P. Manuel (London), Carol P. Millns (Lincoln), I. Mitchell (Airdrie), C. J. Morley (Manchester), Anne Murphy (Louth), C. S. Nelson (Glasgow), J. H. Nirmal (Hartlepool), A. Oakhill (Birmingham), J. P. Osborne (Bristol), G. G. Owens (Liverpool), Barbara Phillips (Manchester), L. Polnay (Nottingham), F. N. Porter (Aberdeen), C. J. Rolles (Southampton), M. Joyce Rubissow (Birmingham), N. Rutter (Nottingham), O. Smales (Nottingham), M. L. Smith (Derby), Olga Stark (London), Ann L. Stewart (London), J. K. Stothers (London), I. L. Swann (Cardiff), Joan M. Tarnoky (Reading), Vivian V. Tracey (Northampton), R. S. Trompeter (London), Shelagh Tyrrell (London), J. Wagget (Newcastle), J. G. Watson (London), R. W. Watt (Wigan), Marjorie E. Watts (London), A. R. Wilkinson (Oxford), M. J. H. Williams (London), M. L. N. Willoughby (Glasgow), Vanessa M. Wright (London), T. D. Yuille (Bristol).

Report of the Council 1978–79

1. OBITUARIES

The Association has suffered the loss of Dr L. O. Abeyaratne, Prof. R. Debré (Honorary Members), Dr C. K. J. Hamilton (Original and Honorary Member), Prof. A. Holzel (Honorary Member), Dr R. J. Isaacs, Dr W. W. Payne (Honorary Member), Prof. H. Valquist (Honorary Member), and Dr H. Parry Williams.

2. DISTINCTIONS

Council has noted with great pleasure that Prof. F. S. W. Brimblecombe has been appointed first chairman of the Joint Committee for Children; Prof. S. D. M. Court has been awarded the Rosen von Rosenstein Medal for 1979; Dr D. Gairdner has been awarded the 1978 Dawson Williams Memorial Prize, Dr H. Jolly the Medical Journalists Award for 1978, and Dr E. M. Widdowson the CBE.

3. COUNCIL

Membership. The following members of the Association have served on Council during 1978–79: Prof. O. H. Wolff (President), Dr E. H. Back, Dr R. D. H. Boyd (Honorary Assistant Secretary), Dr C. G. D. Brook, Dr A. F. Conchie, Dr Barbara Davies, Dr W. Davies, Prof. E. E. Doyle, Dr D. W. Fielding, Dr C. A. S. Galloway, Dr J. R. Harper, Dr A. D. M. Jackson (Honorary Treasurer), Dr G. M. Komrower (President Elect), Dr Sheila Lewis, Dr M. M. Liberman (Honorary Assistant Secretary), Dr J. M. Littlewood, Prof. June K. Lloyd (Honorary Secretary), Dr D. Morris, Dr T. C. Noble, Dr C. H. Nourse (Honorary Assistant Secretary), Dr Aileen Redmond, Dr N. J. Royston, Dr R. A. Shanks, Dr M. J. Simpkiss, Dr H. Simpson, Dr P. E. Walker, Dr B. Wolman, Dr M. H. Bellman (Junior Representative), Prof. D. Hull (Chairman of the Academic Board).

Observers. The Association is grateful to the following for assistance and advice both at Council and in many other ways: Dr Margaret Bell (Scottish Home and Health Department), Prof. F. S. W. Brimblecombe (Member of the Central Health Services Council), Mr A. Jolleys (President of the British Association of Paediatric Surgeons), Prof. T. E. Oppé (Adviser in Child Health, DHSS), Dr Marie Richards (Welsh Office), and Dr Esther Simpson (Department of Health and Social Security).

Meetings. Council met on three occasions: 13 May and 14 October 1978, and 10 February 1979.

4. MATTERS CONCERNING THE ADMINISTRATION OF THE ASSOCIATION

The Association's permanent staff continues to comprise an Executive Secretary and three Assistant Secretaries. It was necessary to take on a temporary secretary for the two months before the 1979 Annual General Meeting to process the booking forms.

The Association would like to record its continuing debt of gratitude to the Institute of Child Health for portering and mailing services, and the use of duplicating facilities and rooms for meetings.

Academic Board. The 13th Annual Report of the Board has been received by Council.

5. AWARDS OF THE ASSOCIATION

James Spence Medal—Prof. Kenneth Cross.

Donald Paterson Prize—Dr R. J. Levinsky.

Heinz Fellowships for 1979–80—Dr M. B. Abdurrahman, Prof. Mrs M. M. Mehta, and Dr S. K. Sen (Fellowship A); Dr C. D. Moyes, Dr A. J. R. Waterston, and Dr R. J. West (Fellowship C). Council is continuingly grateful to H. J. Heinz and Company for their valuable support. The Association remains indebted to the Nuffield Foundation for their advice and administrative help.

6. FINANCE AND ALLIED MATTERS

The Directors of Unigate have again generously donated their annual travel grant of £225 and have supplied the programme and all stationery for the 1979 Annual General Meeting.

The BPA continues to benefit by a share of the profits from the sale of the *Archives of Disease in Childhood*.

7. MEETINGS OF THE ASSOCIATION

The 50th anniversary meeting of the Association was held at York in April 1978. 639 members and guests attended. A special anniversary meeting and dinner was held in London on 7 July 1978. 168 members and guests attended.

Council wishes to record its appreciation to the Academic Board in organising the scientific programme for these meetings and to thank the many members and guests who submitted papers. Council also wishes to thank the conveners and members of specialty groups (12 of which held sessions during the meeting) for their contributions.

The next Annual Meeting of the Association will be held from 15–19 April 1980.

8. STANDING COMMITTEES AND WORKING PARTIES OF THE ASSOCIATION

Reports have been received by Council, and comments have been submitted to government departments and other bodies on many important issues.

This has been a particularly busy year for the Association and Council is deeply grateful to the members who served on committees and working parties and also to those who represented the Association on both statutory and voluntary bodies. Many individual members have helped the Association by their advice, suggestions, and criticisms.

Council wishes to record its special appreciation of the work of the Editors of the *Archives of Disease in Childhood*; the journal continues to be of the greatest value to British paediatrics.

Other agenda items

1. Dr C. H. M. Walker outlined the work of the BPA Health Statistics Sub-committee during 1978 both in the preparation of the BPA *International Classification of Diseases* and its involvement with the Child Health Computing Committee of the DHSS currently investigating methods of medical data storage.
2. The meeting approved the establishment of a category of Associate Membership for Senior Clinical Medical Officers and Clinical Medical Officers whose work is mainly in the field of child health.

SCIENTIFIC PROCEEDINGS

GEORGE FREDERIC STILL LECTURE. The lecture was delivered by Prof. R. J. Haggerty, Roger Irving Lee Professor of Public Health, Harvard School of Public Health, Boston, on 'Life stress, social support, and health'.

National Childhood Encephalopathy Study—a preliminary report. M. H. Bellman, D. L. Miller, P. D. Poore, and E. M. Ross. London.

The National Childhood Encephalopathy Study seeks to assess the relative risk of serious neurological disorders, associated with immunisation, in young children. It also attempts to identify other factors that may cause or predispose to the development of such disorders in immunised and unimmunised children.

A case control analysis was carried out on children between ages 2 months and 3 years admitted to hospital with a defined group of clinical conditions.

In the first year 258 cases were identified. The most common diagnoses were febrile convulsions (34%), encephalitis (26%), and infantile spasms (15%). There was no constant aetiological pattern and in only 10 (4%) cases was the cause clear. The sex ratio was approximately equal, and the age distribution shows a peak at 6 months, with a gradual decline during the next 2½ years. Comparing cases with controls there was no significant difference in the proportion of children immunised within the period of 28 days before admission.

Preliminary results have not identified a significant association between encephalopathy in children and recent immunisation. Although a clinical diagnosis can often be made, there remains a group of children in whom the causal factors and classification of neurological disorder is obscure.

A study of heart rate and rhythm in normal schoolchildren. P. G. B. Johnston, F. Johnston, J. M. Richards, E. A. Shinebourne, and D. P. Southall. Dorchester.

Cardiac arrhythmias associated with sinus node dysfunction have been suggested as a cause of fits, faints, and 'funny turns' in childhood. However information on normal heart rate and rhythm is poorly documented and therefore single 24-hour ECG recordings were performed on 90 randomly selected healthy 7- to 11-year-old children. The mean highest heart rate over 9 beats was 164±16, the mean lowest heart rates were 49±6 over 3 beats and 56±6 over 9 beats' duration. At their lowest heart rates 42 (46%) had intermittent junctional rhythms. One child had episodes of complete 2:1 and Wenckebach A–V nodal block and 7 had intermittent prolongation of the PR interval (>0·20 seconds). 19 had isolated atrial premature beats. In a randomly selected subgroup of 29 children, 23 (79%) had sinoatrial Wenckebach block and 5 (17%) had 2:1 sinoatrial block patterns.

A history and clinical examination was taken on all children studied and this showed no correlation between variations in rhythm and rate and clinical findings. This study demonstrates that normal children exhibit variations in heart rate and rhythm hitherto considered to be abnormal, and therefore normal data must be carefully considered before making a diagnosis of conducting system disorders such as the sick sinus syndrome.

A follow up study of disturbed 3-year olds. P. J. Graham, N. Richman, and J. Stevenson. London.

A total population of 3-year-old children were screened for behaviour disturbance using a standardised procedure of known reliability and validity. Approximately 100 children were identified as showing significant problems and these were matched by sex and social class with a similar number of control children. These children were followed up at 4 and 8 years. Over 90% of the mothers were interviewed at 8 years.

There was a considerable amount of continuity. At 8 years 62% of the 3-year problem group were still disturbed compared with 22% of the controls—a highly significant difference. Independent ratings made by fathers and teachers confirmed that continuity was not merely a function of the mother's perception of the child as disturbed. Family relationships and maternal mental health at 3 years were not good predictors of behavioural outcome at 8 years. Few of the disturbed 8-year olds had been in receipt of any form of professional service.

Findings were discussed in relation to prediction and possible preventive measures for, despite the high level of continuity, only about one-third of disturbed 8-year olds would have been identified on the basis of disturbance at 3 years.

Longitudinal study of overweight children and young adults in the national survey of health and development. O. Stark, E. Atkins, and O. H. Wolff. London.

From the original population of 13 687 children born in one week in March 1946 a cohort of 5362 has been followed at regular intervals. Weights and heights are available at ages 2, 4, 6, 7, 11, 15, 20, and 26 years. A power-type index of weight for height, age, and sex was used as a 'standard' for calculation of percentage overweight and underweight. The prevalence of overweight (defined as $>20\%$ above standard) was 1·6 and 2·8% for males and females respectively at 6 years; 2·0 and 3·7% at 7 years; 6·7 and 9·6% at 11 years; 6·6 and 9·6% at 14½ years; 5·3 and 6·6% at 20 years; and 12·8 and 11·5% at 26 years. Three-quarters of girls and nearly half the boys who were overweight at 6 years were overweight at 26 years and various patterns were noted in the evolution of overweight from childhood to adulthood. In general the risk of being overweight in adulthood increased with the degree of overweight present in childhood. The degree of overweight changed gradually with time so that it exhibited greater stability in the short term than over longer periods.

The correlation between relative weight status in adult life and childhood increases as the child gets older; thus only 10% of the overweight 26-year-old women had been overweight at age 6 years, and this percentage rises to 45% at 14½ years. The corresponding percentages for men are 6 and 28%.

Effects of supplementary vitamin D during pregnancy on Asian women and their infants. O. G. Brooke, C. Bone, I. R. F. Brown, N. D. Carter, D. Maxwell, and V. Robinson. London.

Pregnant Asian women have lower blood levels of vitamin D than Europeans (Dent and Smith, 1969) and their infants are prone to hypocalcaemia (Watney, 1975) and neonatal rickets (Ford *et al.*, 1973). We therefore investigated the effect of vitamin D supplements during pregnancy in a group of Asian women and their infants. Ergocalciferol, 1000 IU/day, or placebo were given by random allocation to 61 Asians during the last trimester. The trial was double blind. Blood calcium, phosphate, alkaline phosphatase, 25-hydroxycholecalciferol (25-OHD), and vitamin D binding globulin (VDBG) were measured on entry to the trial, after delivery, and in cord blood. Infant blood calcium was measured on day 3 and 6, and fetal growth was assessed by anthropometry. The following results were obtained. (1) Mean plasma 25-OHD declined in late pregnancy in the control group and was very low in cord and postpartum blood (9 and 12 nmol/l respectively). (2) The treated group had significantly higher mean plasma 25-OHD in cord and postpartum blood (110 and 153 nmol/l). (3) There was a positive correlation between maternal and cord blood 25-OHD ($r=0{\cdot}92$, $P<0{\cdot}001$). (4) Alkaline phosphatase levels were lower in the treated than the control group, both in maternal and cord blood ($P<0{\cdot}05$). (5) There was no difference between treated and control groups in fetal growth, neonatal calcium levels, or maternal and infant VDBG levels.

We conclude that, while vitamin D supplements may be necessary in Asians to prevent deficiency during pregnancy, they do not influence fetal growth or neonatal calcium levels.

What can be expected from growth hormone therapy? W. Hamilton. Glasgow.

The clearance rate of administered human growth hormone (hGH(UK)) was studied in 12 children who were receiving hGH(UK) for short stature due to isolated growth hormone deficiency.

Administration of hGH stimulates a rise in plasma cortisol, and gives an 'effective' plasma level of hGH from 2·5 to 6 h postinjection. The high level of plasma oestradiol suggests that administered hGH (or an impurity) stimulates ovarian function. Likewise the levels of T3 and T4 with a normal TSH level suggests possible chronic thyroid stimulation from the hGH.

These findings stimulated an analysis of the clinical data on 29 children treated with hGH for short stature over 2 to 4 years. Only 2 boys out of 20 crossed the 3rd centile upwards; 18 did not increase significantly their growth velocity. When height was charted in relation to bone age, bone age accelerated faster than increments in height were obtained. Similar findings were observed in 9 girls (charts available).

These data suggest that hGH (or an impurity) accelerates osseous maturation, either via thyroid or gonadal stimulation, to a greater degree than it increases linear growth.

The physical, biochemical, and immunological status of hGH(UK) was therefore defined. The conclusions are that hGH(UK) contains up to 50% polymer (likely to reduce total growth stimulating effects) and a measurable amount of both LH and FSH (stimulants of gonadal activity). The net effects predictable therefore are early osseous fusion (from gonadal stimulation) and a restriction in the rate of linear growth (only 50% of the dose administered effective). Thus it can be expected that ultimate short stature (in most cases less than 3rd centile) is likely to result from the treatment of patients with short stature with hGH(UK).

Temperature control in incubators. J. K. Stothers and K. W. Cross. London.

Abdominal skin temperature is commonly used to govern the environmental temperature in servo-controlled incubators. Ill babies are frequently nursed prone, thus insulating the abdomen, rendering it thermally unresponsive to external temperature change and unrepresentative of general surface temperature which governs sensory input and response.

It therefore seemed desirable to find a site responsive to environmental temperature change and representative of mean skin temperature. Both thermographic (Clark *et al.*, 1978) and thermocouple measuring systems were used. The infants were nursed prone in a Vickers incubator (model 79) while temperatures were recorded at 9 sites using the thermocouple thermometer. When possible, infrared thermograms were filmed simultaneously.

Both methods gave similar values of mean skin temperatures, and the upper arm and thigh were found to approximate closely to the mean. In addition, they responded well to environmental temperature changes.

These findings suggest that if incubators are to be used in the servo mode, and this is in itself questionable, the above sites would be more suitable for sensor placement than the insulated abdominal skin of the prone infant.

Early diagnosis of group B streptococcal disease in the newborn.•M. J. Lewins and J. Dodge. Cardiff.

A review of 14 infants admitted to the neonatal intensive care unit of the Hospital for Sick Children, Toronto, with early group B streptococcal (GBS) disease demonstrated the difficulty of establishing a clinical diagnosis from the history, examination, and chest *x*-ray. All infants were initially diagnosed as having respiratory distress syndrome (RDS).

Nine of these infants died. All infants who had apnoeic episodes before antibiotic therapy died. Those infants who survived received antibiotics at a significantly earlier age but were otherwise similar to the group who died.

In a subsequent prospective study, all infants admitted with a provisional diagnosis of RDS had their gastric contents aspirated and the aspirate subjected to culture, Gram staining, and a 'shake test' for surfactant activity. All the infants also had blood cultures and differential white cell counts. All received antibiotics. In this time 6 infants were identified as having GBS within an hour of admission. Four of these infants survived.

It is concluded that these methods offer the opportunity for early clinical diagnosis of GBS and, with early antibiotic therapy, may reduce mortality from the disease.

Prevention of thalassaemia major by antenatal diagnosis. B. Modell, M. A. Angastiniotis, D. V. I. Fairweather, M. Matzabio, and R. H. T. Ward. London.

Prevention of thalassaemia major by antenatal diagnosis, using fetal blood samples obtained at 18–22 weeks' gestation, is now an established procedure: 170 cases have been managed at UCH. There are 2 methods for fetal blood sampling: blind needling of the placenta carries a 7% risk of immediate intrauterine death, while fetoscopy, with fetal blood sampling, appears to carry a 15–20% risk of premature labour with its attendant problems. There is an approximately 1% risk of laboratory misdiagnosis—that is, confusion between thalassaemia major and thalassaemia trait. As married couples at risk for thalassaemia major infants can be detected before they have had an affected child, such couples should now be sought in the antenatal clinic (and possibly before they reach this stage), so that they can receive genetic counselling and consider the offer of antenatal diagnosis. The response of at-risk couples to this offer differs widely between the two affected communities in Britain. Nearly 100% of Cypriots request antenatal diagnosis, while about

60% of Indian/Pakistani couples do so. This cultural contrast gives some guidance about the most desirable methods of screening populations for carriers. This work has wider implications in that it provides a small-scale model for the attitudes and requirements of the British population when antenatal diagnosis for endemic common inherited diseases, such as fibrocystic disease and phenylketonuria becomes available, as is likely in the next few years.

Problems of antenatal screening of a total population for neural tube malformations. K. M. Laurence, K. Evans, B. Hibbard, and C. J. Roberts. Cardiff.

Although the collaborative survey shows that prenatal detection using serum alphafeto protein estimated at 16–18 weeks is feasible, the problems of introducing and conducting a population screening programme have not been identified. A screening programme was set up, based on all the pregnancies in mid-Glamorgan from 1977 to investigate the problem. The following comments are based on the first 3330 completed pregnancies by the end of the first 6 months.

Successful population screening depends on a good laboratory, genetic counselling, transport, communication and co-operation with staff, and compliance of the mothers. An efficient supra-regional radioimmunoassay laboratory is essential. Genetic counselling services have to cope not only with preamniocentesis and pre- and postabortion counselling, but also with the other problems coming to light during screening. Efficient transport of specimens to the laboratory and reports back to the clinics and consultants is essential. Communication between clinics, laboratory, obstetricians, GPs, genetic clinics, etc., is vital. Good compliance of patients' understanding the aims of screening, attending early enough for this to be instituted, and GPs being co-operative and referring early enough to the clinic, is one key to success. An efficient ultrasound to date pregnancies accurately and competent amniocentesis with few sequential abortions are essential. With serum samples taken between 16 and 18 weeks, amniocentesis tends to be carried out when discrimination between normal and abnormal AFP values become blurred. This leads to possible problems of both false-positive and negative. Obstetricians sometimes deviate from usual procedures which may also lead to tragedy.

Well conducted screening can reduce the number of babies with neural tube malformations reaching term to less than 10%, leading to a considerable saving of paediatric resources and prevention of much family anguish.

Diagnosis of vesico-ureteric reflux without bladder catheterisation. S. T. Meller, H. B. Eckstein, and B. C. H. Ward. Carshalton.

The method of indirect radionuclide cystography (RNC) is described. The urinary tract is imaged with a gamma camera after intravenous administration of a technetium-labelled chelate. When the bladder is full the child is required to void on request. Reflux which reaches the renal pelvis will generally be recognised from the analogue gamma camera images. Using a small computer to store digital images and to generate time/activity curves from the kidneys and bladder improves the diagnostic accuracy. Spontaneous reflux during bladder filling may also be recognised.

25 children, aged 3 to 12 years, first had standard radiological investigation—an intravenous urogram and micturating cystourethrogram (MCU)—and were then referred for RNC. They were examined by one observer without prior knowledge of the radiological findings. Six children were unable to void on request. Three studies were spoiled by movement artefact. In 14 examinations (23 normal units and 5 refluxing units) the MCU and RNC proved to be in accord. In 2 cases there were conflicting results.

The RNC avoids the trauma of bladder catheterisation and provides a physiological approach to the diagnosis of reflux. The radiation exposure is significantly reduced. We recommend the use of this technique in selected cases.

Renal growth following unilateral antireflux surgery. J. D. Atwell and P. Cox. Southampton.

112 children treated surgically for unilateral vesicoureteric reflux at the Wessex Regional Centre between 1969 and 1975 were reviewed. The ages of the patients ranged from one month to 13 years and the mean length of follow-up was 3 years 11 months. Renal growth was assessed in each patient by measurements of renal length from serial intravenous pyelograms performed preoperatively and at intervals during the period of follow up.

Calculations of the mean renal lengths preoperatively and at 3 months, 1 year, and 5 years postoperatively suggest that renal growth accelerates after successful reimplantation of the ureter. The phase of rapid renal growth was confined to the first postoperative year and is greatest in the first 3 months after antireflux surgery and was equal in both kidneys. The mechanisms accounting for these alterations in renal growth remain obscure.

Adhesion of Enterobacteriaceae to buccal epithelial cells.

D. Candy, J. T. Harries, T. S. M. Leung, W. C. Marshall, and A. Phillips. London.

The pathophysiology of infantile diarrhoea is currently under intense investigation particularly in relation to adhesion of bacteria to the alimentary tract, which we have studied using human buccal epithelial cells (BEC).

A pathogenic strain of *Escherichia coli* (O26:K60) known to adhere to human fetal intestine (McNeish *et al.*, 1975) adhered to adult BEC, while a nonpathogenic, nonadhesive strain (O1:K1) did not. Adhesion was temperature-dependent, correlated with fimbriae production, and was inhibited by breast milk. Serotypable *E. coli* from stools of 7 infants with acute diarrhoea, and *E. coli, Enterobacter* sp., *Proteus* sp. (and *Candida albicans*) from the small intestine of 3 infants with protracted diarrhoea, adhered to BEC from 6/7 and 3/3 of the infants' BEC respectively. The nonadhesive *E. coli* (O1:K1) adhered to BEC from the latter group. Adhesion of all *Enterobacteriaceae* was inhibited by D-mannose.

Our results indicate that BEC provide a simple model for studying intestinal adhesion of bacteria in man, and suggest that adhesion may be mediated by mannose-like receptors. Moreover, the test system has the important advantage that bacteria can be studied with cells from affected cases, and thus may provide a means of assessing the 'enteropathogenicity' of bacteria in individual patients.

A spoonful of sugar helps the medicine go down.

I. F. Roberts and G. Roberts. London.

The aim of this study was to see if chronic administration of liquid medicines sweetened with sucrose had a deleterious effect on children's teeth. The teeth of a group of 44 children aged less than 6 years who had been taking syrup medicines regularly for at least 6 months were compared with those of a control group of 47 children of similar ages. Dental decay was assessed, using established dental formulae, by measuring their carious index, plaque index, and gingival index. The dentist's ability to be consistent in his measurement of dental decay was checked by performing repeatability tests; analysis of these using the Spearman's rank correlation coefficient indicated that the clinical findings were sufficiently reliable for the purpose of this study. A questionnaire, related to other factors known to children's deciduous teeth was completed at the end of each dental examination.

The children who received sucrose-based medicine had more carious teeth ($P<0{\cdot}05$) and more gingivitis ($P<0{\cdot}05$, Mann-Whitney U test). Information obtained from the questionnaire was analysed using the χ^2 test, and showed no difference between the two groups for cariogenic factors unrelated to medicines.

It is concluded that sucrose-based medicine regularly administered to children for 6 months cause dental caries and gingivitis. Liquid medicines for children should therefore be either unsweetened or sweetened with noncariogenic substances.

Bone marrow relapse on treatment in childhood acute lymphoblastic leukaemia.

J. James, J. H. Baumer, B. Howlett, P. J. Kearney, and M. G. Mott. Bristol.

A retrospective study was carried out on children with acute lymphoblastic leukaemia having their first relapse in the bone marrow while on treatment. Among 190 children from 9 major centres in the United Kingdom, there were no long-term survivors. The median durations of complete and haematological remission were 80 and 97 days respectively. The risk of developing meningeal leukaemia in the second remission was 46·1% and for overt testicular infiltration in boys was 15·7%. The main factor at diagnosis affecting outcome was the initial total white blood count. Children with a high white count relapsed earlier while on treatment and survived for a shorter period of time after relapse, with shorter duration of the second remission. They achieved a second remission as readily as children with low initial white blood counts. These effects appeared to be dependent on the T-cell status of the leukaemia.

There was a group of children in whom a first remission was achieved only with difficulty, who were particularly resistant to treatment after relapse. The majority of children who attained a second remission did so within 12 weeks of relapse. There were a few children who survived for periods up to one year in relapse, however. Children who had not received vincristine and prednisolone as maintenance therapy before relapse were more likely to achieve a second remission. Those children who were resistant to the more commonly used drugs also appeared to be resistant to other groups of drugs. We conclude that children who end their first remission with relapse in their bone marrow while still receiving treatment are not curable by present chemotherapeutic regimens. Any attempt at improving this situation (for example, by bone marrow transplant) will need to take account of the high risk of CNS leukaemia subsequently developing in these children.

Meeting held on 29 June 1979 at the University of Glasgow

The female advantage in fetal lung maturation. M. E. Avery, J. S. Torday, H. C. Nielsen, M. Fencl, and R. V. Kotas. Department of Pediatrics, Harvard Medical School, Boston, and Tulsa, USA.

Male infants have a 1·7 times greater mortality rate from RDS than female ones. If the disorder is a reflection of immaturity with respect to pulmonary surfactant, then the lungs of female infants should be relatively more mature than those of male infants at a given gestational age. Naeye found that at between 25 and 32 weeks' gestation, female infant lungs were more mature by histological criteria (Naeye *et al.*, 1971). Further support for relatively greater maturity of female fetal lungs comes from an analysis of L/S ratios and cortisol in amniotic liquid from 167 pregnancies of 28–42 weeks, complicated and uncomplicated. At all stages of gestation, males had a lower L/S ratio than females. Lower cortisol levels were also noted in male infants. In an analysis of pressure-volume relationships in fetal rabbit lungs, the female fetuses retained more air at a given transpulmonary pressure than littermate males of 27 days' gestation, which is consistent with greater maturity. The response to glucocorticoid administration was also greater in the lungs of the female fetal rabbits. These observations support the hypothesis that the lung in the female fetus is more mature than that of the male.

Gut hormones in the neonate. T. E. Adrian, A. Aynsley-Green, S. R. Bloom, and A. Lucas. Department of Paediatrics, John Radcliffe Hospital, Oxford, and Department of Medicine, Royal Postgraduate Medical School, Hammersmith Hospital, London.

Gut hormones exert important effects on gut growth, secretion, motility, and on intermediary metabolism, and may play a key role in the postnatal adaptations to enteral feeding. Using sensitive radioimmunoassays we have measured 10 entero-insular hormones in the plasmas of (a) 203 healthy term or preterm infants at birth or during the first 24 days of life, either before or at 30, 60, or 120 minutes after feeding, and (b) 10 6-day-old preterm neonates who had never been fed orally as they had hyaline membrane disease. Each infant contributed only one plasma sample, removed at the time of a routine clinical blood test. Basal levels of gastric inhibitory polypeptide (GIP), pancreatic polypeptide (PP), enteroglucagon (EG), neurotensin (NT), motilin, and gastrin all rose steeply during the neonatal period, reaching levels which exceeded those in healthy, fasting adults. In contrast, plasma concentrations of GIP, EG, NT, motilin, and gastrin did not show postnatal increases in the unfed group of infants. In addition, for 8 hormones (secretin, GIP, PP, NT, EG, motilin, gastrin, and insulin) we observed a progressive postnatal increase in the endocrine response to a feed. Profound changes occur therefore in gut hormone physiology after birth, and these changes may in part be due to enteral feeding itself. These data are relevant to the design of optimal feeding regimens for high-risk neonates.

The neonatal breast. J. McKiernan and D. Hull. Department of Child Health, Nottingham University.

A study has been made of breast development in the newborn infant. The diameter of the breast nodule was measured in 288 infants during the first 2 days of life. The values came within a normal distribution. In 149 male infants, mean birthweight 3·37 kg, the breast diameter was 7·54±0·25 (mean± SE), and in the 139 females, mean birthweight 3·19 kg, the breast diameter was 7·98±0·24 (mean±SE).

Breast size was also assessed in 115 low birthweight infants. In infants below expected body weight, 'small-for-dates' (SGA), the breast diameter was greater than that of infants of similar bodyweights but appropriate for gestational age (AGA).

The timing of onset of milk secretion by the neonatal breast has also been examined. Secretion began on the 6th to 8th day of life in 11 mature infants. Interestingly, of 13 SGA infants who were 'secretors', 11 were secreting on the 5th day or earlier. Delayed onset of secretion was noted in a small number of preterm, low birthweight infants. Some mature infants did not secrete milk.

Considerable breast engorgement, greatest in the 2nd and 3rd weeks of life, was found in healthy infants. There was a positive correlation between breast diameter on day 6 and plasma prolactin at this time ($R=0\cdot84$, $P<0\cdot001$).

The study of the neonatal breast and its secretions offers interesting insights into aspects of fetal and neonatal endocrinology and nutrition.

What do we know about resorption and conversion of vitamin D3 in premature infants? H. Wolf, G. Offermann, and V. Gräff (introduced by E. Widdowson). Department of Neonatology, Universität Giessen, and Department of Nephrology, Klinikum Steglitz, Freie Universität Berlin, West Germany.

The necessary supplementation of vitamin D3 is higher for premature infants than for term ones (1000 IU v. 500 IU a day). 1000 IU (25 μg) of vitamin D3 are equivalent to 9 μg or less of 25-(OH)-D_3 (Wolf *et al.*, 1975). Therefore the question arises whether resorption or conversion to 25-(OH)-D_3 is hampered in the premature infant.

Four groups of premature infants were observed during a 3- to 5-week period. In the control group (gestational ages 32 to 38 weeks) a vitamin D3-free formula (Meb-milupa) was given. The level of 25-(OH)-D_3 in plasma remained low (10 ng/ml; 25 nmol/l). The second group (GA 32 to 34 weeks) received 1000 IU vitamin D3 daily. The plasma level of 25-(OH)-D_3 rose to 25 ng/ml (62 nmol/l). The third group (GA 36 to 38 weeks) also received 1000 IU vitamin D3. This resulted in a 'calculated' level of 25-(OH)-D_3 up to 75 ng/ml (187 nmol/l) after 9 weeks. However, the same level was reached after only 3 weeks in a fourth group of infants of the same GA given 1000 IU vitamin D3 and small amounts of supplemental breast milk (up to 200 ml a day). These findings suggest that either resorption of vitamin D3 or its conversion to 25-(OH)-D_3 is diminished in the immature infant. Resorption may be enhanced by breast milk.

Ionised calcium in pregnancy. N. R. Belton, M. J. Forsyth, M. M. Giles, R. Elton, and J. O. Forfar. Department of Child Life and Health, University of Edinburgh, and Simpson Memorial Maternity Pavilion, Royal Infirmary, Edinburgh.

Vitamin D requirement during pregnancy has not been definitively established. Supplementary vitamin D (1000 IU a day), or a placebo, was given to two groups of pregnant women from the 12th week until delivery, and total Ca, ionised Ca, total protein, Mg, and P measured in plasma at 12 weeks, 24 weeks, 34 weeks, and delivery in both maternal venous blood and cord blood. Ionised Ca (mmol/l), measured using the Orion SS-20 analyser was (mean±SD and normal):

	Supplemented group	*Control group*
12 weeks (combined groups)	0·93±0·09 (45)	
24 weeks	0·89±0·08 (24)	0·91±0·08 (22)
34 weeks	0·87±0·11 (38)	0·87±0·09 (32)
Delivery	0·86±0·10 (7)	0·77±0·11 (11)
Maternal vein		
Unbilical vein	1·05±0·16 (8)	0·97±0·10 (11)
Umbilical artery	0·91±0·17 (7)	0·87±0·16 (8)

Thus ionised Ca decreased during pregnancy (difference between 12-week and delivery values in unsupplemented group was highly significant, $P<0\cdot001$). Umbilical venous values were higher than maternal delivery values in both groups.

During pregnancy total Ca concentration tended to increase in both groups with no correlation between ionised and total Ca except at delivery (maternal values positively correlated).

The percentage of ionised relative to total Ca decreased during pregnancy, being significant in the unsupplemented group (39·5 to 31·8%; $P<0\cdot001$).

Ionised Ca does not have a constant relationship to total Ca during pregnancy.

An enzymic polarographic sensor for continuous measurement of glucose concentration *in vivo*. R. M. Gardiner and I. A. Silver. Physiological Laboratory, Cambridge, and Department of Pathology, University of Bristol Medical School, Bristol.

The hydrogen peroxide generated as glucose reacts with oxygen in the presence of glucose oxidase can be measured at a platinum anode, and a glucose sensor based on this principle has been described (Clark and Clark, 1973). A modification of the Clark glucose electrode has been designed which is small enough for intravascular use.

A 1·0 mm length of Teflon-coated platinum iridium alloy wire (bare diameter 175 µm) is stripped of Teflon, lightly platinised, and dipped into an aqueous solution of catalase-free glucose oxidase. The active tip is subsequently treated in cold 1% glutaraldehyde, and a membrane applied by dipping in cellulose di-acetate. The electrode is maintained at a potential of +700 mV with respect to a sintered silver–silver chloride reference electrode.

Its characteristics have been investigated *in vitro* during immersion in well-stirred plasma at 38°C. Response times (95% of step change) range from 6 to 30 seconds depending on membrane thickness, and the response is linear within the physiological range of glucose concentrations (1–10 mmol/l). Recordings have been made *in vivo* of the changes in blood glucose concentration which follow administration of insulin, adrenaline, and glucose in the heparinised calf and lamb.

Sucking patterns of human babies at the breast. R. F. Drewett, A. Bowen-Jones, and M. Woolridge (introduced by J. D. Baum). Department of Psychology, University of Durham, and Department of Paediatrics, John Radcliffe Hospital, Oxford.

Studies of sucking patterns using bottles are of limited value in research on breast feeding, as they do not allow the sucking of the baby to be related to its natural consequence (the stimulation of the milk ejection reflex). We report an analysis of sucking on the breast made by filming the mouth of the baby.

Intersuck intervals fall on two distinct distributions, one of short intervals (<1·3 seconds) corresponding to the period of sucking, the other of longer intervals (>1·3 seconds) corresponding to pauses between bursts of sucking. The proportion of long intervals increases as the breast empties. In studies combining test weighing and sucking rate determinations the rate of sucking (within bursts) was found to increase as milk flow decreased.

These studies show, contrary to results derived from bottle feeding, that there is no simple dichotomy between 'nutritive' and 'non-nutritive' sucking, but rather that there is a single gradient of sucking rate of which these types represent the two extremes. The reflection of milk flow in the sucking pattern of the baby may be of use in clinical evaluation of breast-feeding difficulties.

Human milk cell concentration after storage in glass and plastic containers. C. Burns, D. M. Flynn, J. Kendra, and M. Szawatoski. The Royal Free Hospital, London.

Expressed breast milk is often stored without precautions being taken to conserve the cell content. Typically it is stored in glass vessels, although milk macrophages have been shown to have glass-adhesive properties (Smith and Goldman, 1968).

We investigated the concentration of human milk cells after storage in glass and polystyrene containers. 10 30-ml samples of milk were collected from nursing mothers. 10 ml of each sample was immediately examined for cellular concentration (control). 10 ml was stored in a glass test-tube and 10 ml in a polystyrene test-tube at 4°C for 8–16 hours before the cell concentration was established.

The mean cell count of the samples stored in polystyrene was 83% of the control, while the mean cell count of the samples stored in glass was 54% ($P<0·001$, paired *t* test). Differential cell counting showed that in the polystyrene-stored samples the proportion of macrophages and lymphocytes was greater than in the glass-stored samples; the reverse was true for the neutrophils. No tests were performed to assess the viability of the cells.

If human milk cells are considered of importance it is suggested that expressed breast milk be stored in polystyrene, or possibly other plastic containers, rather than in glass.

Use of doxapram in apnoea and hypoventilation in the neonate. J. E. H. Brice, A. W. Boon, and A. D. Milner. Department of Neonatal Medicine, City Hospital, Nottingham.

Three cases are reported in which doxapram was used to stimulate respiration in the neonate. The first two were very low birthweight, preterm infants with recurrent apnoea, not responding to oral theophylline and requiring assisted ventilation. The first had recurrent apnoea on withdrawing ventilation that was abolished for 15–25 minutes after each of 3 intravenous injections (0·5 mg) of doxapram. The second infant was given IV doxapram (1 mg bolus, followed by 0·5–1 mg/hour) to try to avoid a further period of assisted ventilation. A definite reduction in apnoea occurred but jittery movements were noted, probably related to the doxapram. The third case was a term infant with severe hypoventilation requiring assisted ventilation from the first day. All attempts to withdraw ventilation were unsuccessful until 5 days, when IV doxapram (5–10 mg bolus and hourly infusion) was administered with a striking improvement in spontaneous respiration. The doxapram was stopped two days later because of abnormal neurological signs, and the baby died.

These preliminary results suggest that doxapram is a more powerful respiratory stimulant than theophylline in the neonate and may have a place in the management of apnoea of prematurity. Little is known about the metabolism of doxapram, and possible side effects indicate that until further evaluated it should be used only when other established treatments have failed, and should be started in smaller doses than reported here.

Comparison of IV salbutamol with IV aminophylline in severe acute asthma

Sir,

In a double-blind comparative study of children with acute asthma, Hambleton and Stone (*Archives*, 1979, **54**, 391) showed that IV salbutamol and aminophylline were equally effective when given during the first 24 hours.

The optimal use of theophylline requires a dosage regimen that maintains the serum concentration within the therapeutic range of 10–20 mg/l (Jenne *et al.*, 1972; Weinberger and Bronsky, 1974). Hambleton and Stone used a loading dose of 4 mg/kg followed by 0·6 mg/kg per hour. In a recent study (Selvig *et al.*, 1979), despite a bigger loading dose of 5 mg/kg in slightly older children (aged 8–15 years), therapeutic values were reached in only 62% of them and maximum serum concentration in each case was in the lower half of the range. A more suitable loading dose would have been 7·5 mg/kg, which is tolerated by most children, with average serum concentrations in the middle of the range (Weinberger, 1978). Furthermore, the infusion rate of 0·6 mg/kg per hour is much lower than the 0·85 mg/kg per hour recommended to maintain therapeutic serum concentrations in children less than 9 years (Hendeles and Weinberger, 1979).

The similar clinical effect shown by Hambleton and Stone when aminophylline dosage was subtherapeutic suggests to us that a different conclusion might have been reached had a therapeutic dose of aminophylline been used.

Drs Hambleton and Stone comment:

We note the criticism about the dose of aminophylline and make the following comments. The assertion that therapeutic efficacy will be achieved when serum theophylline is 10–20 mg/l is based on the use of *oral* theophylline compounds in the prophylaxis of *perennial* asthma (Jenne *et al.*, 1972; Weinberger and Bronsky, 1974). Weinberger *et al.* (1976) gave data on *acute asthma* in children and evaluated the dosages necessary to maintain the above level. However, their paper did not indicate how effective their regimen was in terms of producing relief from asthma. Turner-Warwick (1957) studied acute wheezing in adults, and judged the appropriate serum levels simply from reports from patients on the subjective relief of symptoms after oral theophylline compounds. Selvig *et al.* (1979) studied serum theophylline levels after a single IV dose of aminophylline, and recommended a loading dose of 6 mg/kg but gave no information about maintenance treatment. Weinberger (1978) recommended a loading dose of aminophylline 5 mg/kg, and although he suggested 7·5 mg/kg in some children he pointed out that this dose would be toxic in others. Weinberger (1978) and Hendeles and Weinberger (1979) recommended 0·8 mg/kg per hour and 0·85 mg/kg per hour respectively as maintenance therapy, but gave no indication that these doses were necessary for relief of symptoms in *acute* asthma. They recommended that serial theophylline estimations should be carried out for patients individually, which is the ideal *modus operandi.*

In a double-blind trial such as ours, serum theophylline estimations during treatment are precluded. Pierson *et al.* (1974) used virtually the same dosage regimen as we did, and produced objective evidence that this was effective in acute asthma. In routine practice we have also found this regimen effective and so adopted it for the trial, being confident that there would be no side effects. It also facilitated the pharmaceutical preparation of our ampoules for the double-blind design, having regard to the dosage of salbutamol. We feel our results support those of Pierson *et al.* (1974) by providing objective evidence that this regimen is effective in acute asthma. The assertion that our dose of aminophylline is subtherapeutic is not justifiable. It is possible that a higher dose might have been more effective, but another double-blind trial would be necessary to establish this point.

Lomotil in diarrhoeal illnesses

Sir,

The article by Curtis and Goel (*Archives*, 1979, **54**, 222) prompts me to place the usage of Lomotil in young children in the tropics in its right perspective. The problems of diarrhoea in the tropics are quite different when compared with temperate climates, and management of this condition is therefore also different.

In situations where children have little or no access to optimal therapeutic management, especially fluid therapy, symptomatic control of diarrhoea does become important and it is in this context that I find little objective evidence for Curtis and Goel to draw a general conclusion that the use of Lomotil is difficult to justify in children.

In their study only 6 of 45 patients had actually been prescribed Lomotil for a diarrhoeal illness, of which 4 took an accidental overdose. The remaining 39 children had ingested large quantities of the drug accidentally without any indication for its use, when adult relatives had been prescribed the drug. The authors state that no correlation was found between severity of symptoms and dose ingested, but the upper limits of dose range in their paper show that in the mild, moderate, and severe cases the quantity of drug ingested was 23 times, 33 times, and 40 times the therapeutically recommended dose.

Some time ago we were equally concerned about the use of Lomotil and so we conducted a dose response study in children suffering from nonspecific and specific diarrhoea (Karan *et al.*, 1976), using Lomotil in a dosage range of 0·2 to 0·3 mg/kg, and observed that the optimal dose for Indian children appears to be about 0·25 mg/kg. Furthermore, when used in this therapeutic dose there were no significant side effects or signs of toxicity, although children taking 0·3 mg/kg did have slightly more side effects, but these were not statistically significant.

I feel that Lomotil does have a role in managing diarrhoea in the tropics if used judiciously, but problems can arise if the correct dose is not given. Accidental overdosage can of course occur with any drug.

Hyderabad 2,
Andhra Pradesh, India

Sir,

This letter is in response to the paper by Curtis and Goel (*Archives*, 1979, **54**, 222). While I agree that there is a need to monitor Lomotil therapy in young children closely, our experience with this drug in this country does not justify their conclusions.

Curtis and Goel state that in only 13% (6 out of 45) cases was Lomotil actually prescribed for a diarrhoeal illness, and in the remaining 87% a large quantity of the drug was ingested by small children, where the drug was not prescribed primarily for them. Even in the former group, 4 of the 6 cases had an accidental overdose.

Bovier-Lapierre *et al.* (1973), Scorza *et al.* (1974), and Wasserman (*Journal of the American Medical Association*, 1974) clearly differentiate the incidence of intolerance and intoxication. Although the former can occur with lower doses in children who are hypersensitive to the drug, the total incidence of such effects is relatively low compared with the intoxication effects seen after accidental ingestion of large doses and this is very much a dose-related effect. It surprises me that Curtis and Goel do not think this is so, because the upper limits of the dosage range in their own data are 5·8, 8·4, and 10 mg/kg respectively, in the mild, moderate, and severe cases, compared with the therapeutic dose of 0·25 mg/kg.

Morbidity and mortality from diarrhoea in the tropics is such that rapid control of diarrhoeal symptoms becomes mandatory and the rationale of management becomes slightly different from the one seen in other parts of the world. It is in such a setting that we evaluated the role of Lomotil in diarrhoea in children below 2 years (Limaye, 1979); we found that the judicious use of this drug did not result in any undue toxicity.

Lomotil is certainly no panacea for diarrhoea but it does offer the paediatrician, at least in the tropics, a useful mode of speedy correction of diarrhoeal symptoms. However, we agree with Curtis and Goel that when prescribed for adult relatives, the drug should be kept out of reach of children.

Dr Goel comments:

It was certainly not our intention to exclude the use of Lomotil as an antidiarrhoeal agent in children in the tropics. No doubt all who treat such children would agree that the mainstay of treatment of diarrhoea in children in any part of the world is the correction of fluid, electrolyte, and acid-base status, and not the reduction of intestinal motility by an antidiarrhoeal agent. If, as suggested by Dr Karan, such therapeutic measures are not available, then perhaps one could use an antidiarrhoeal drug, such as Lomotil, though only with caution. This is because, in our experience, it is not possible to predict what dose will be toxic in children.

Both Dr Karan and Dr Limaye emphasise that in our cases severity of the symptoms was related to the dose ingested, and they also imply that symptoms only occur above a recommended therapeutic dose 0·25 mg/kg a day. But they fail to observe that on the contrary the figures for the lower limit of the ingested dose (mild, 0·62 mg/kg; moderate, 0·25 mg/kg; and severe, 0·77 mg/kg) did not correlate with the severity of symptoms. We suggest that if it is necessary to use Lomotil the prescribing doctor should take cognisance of the risks.

Infantile cortical hyperostosis with raised immunoglobulins

Sir,

Ramchander and Ramkissoon (*Archives*, 1978, **53**, 426) drew attention to the IgA and IgM levels in 2 cases of infantile cortical hyperostosis (Roske-de Toni-Caffey syndrome). They said that a virus infection during intrauterine or neonatal life might be the cause of this disorder.

I know 2 Italian families in which this disease was diagnosed in two generations: in the first family, in the mother and her son; in the other family, the father, the daughter, and the father's first-cousin all had the disease (Duillo and Cerruti Mainardi, 1969). A few months ago another girl was born in the second family, and she shows the same disorder at age 8 weeks.

These cases, as do many other familial ones in the literature, support de Toni's hypothesis (de Toni, 1943) that genetic factors may play a rolè in the aetiology of this mysterious disease.

Polyarthritis associated with Wilson's disease

Sir,

A 14-year-old boy was admitted to hospital in August 1978 with an acute attack of polyarthritis which he had had for one day, and which affected both knees and elbows. There was no history of sore throat, and the family history was unremarkable. On examination he was pale, and the affected joints showed effusion with tenderness and heat. Small spider telangiectases were present over the upper sternum, and both spleen and liver were slightly enlarged. Slit-lamp examination showed Kayser Fleischer rings in both corneae.

Full blood picture, ESR, urine analysis, liver function tests, ECG, serum urate, Hb electrophoresis, C-reactive protein, latex-fixation test, throat swab culture, lupus erythematosus phenomenon, were all negative. ASO titre, 333 IU/ml. Percutaneous liver needle biospy showed fatty changes. Serum copper 77·96 μg/100 ml (12 μmol/l), serum caeruloplasmin 105 mg/l (10·5 mg/100 ml), urinary copper 261 μg/24h (4·09 μmol/24h).

The boy subsequently developed two further attacks of polyarthritis during the next 2 months; the findings and investigations then were similar with ASO titre 166 and 250 IU/ml.

He responded well to paracetamol initially, and was then put on D-penicillamine, when he remained well until last seen in June 1979.

The association of polyarthritis with Wilson's disease has not been previously reported, and may have been coincidental, but slit-lamp examination of atypical cases of arthritis in children would be prudent.

Sodium valproate, pregnancy, and neonatal hyperglycinaemia

Sir,

It has been demonstrated that sodium valproate (SV) crosses the placenta freely and that maternal serum levels will reflect fetal serum levels (*Archives*, 1979, **54**, 240). The SV concentration in the serum of a neonate was of the same order as that of the mother's at delivery, but fell to insignificant levels by 5 days and was undetectable at 29 days. As this child appeared healthy, it was concluded that the use of SV in pregnancy was safe.

On the other hand, administration of SV is known to cause hyperglycinaemia and hyperglycinuria in patients suffering from epilepsy (Jaeken *et al.*, 1977; Kamoun and Parvy, 1978; Similä *et al.*, 1979). In experiments on animals it has been shown that the rate of influx of glycine and other amino-acids into the brain is higher in the newborn period than later in life (Seta *et al.*, 1972; Banos *et al.*, 1978). In addition, high concentrations of glycine, which are found in nonketotic hyperglycinaemia and many organic acidaemias, are associated with severe impairment of neuronal function, and therefore a high plasma level of glycine during early postnatal life may be a risk factor (Tanaka, 1975; von Wendt *et al.*, 1978). Therefore, we monitored the clinical state and the levels of plasma glycine and serum SV postnatally in 2 neonates; in both, the mothers had received SV treatment during pregnancy.

Case 1

A 25-year-old woman, II para, in whom epilepsy had been diagnosed in 1972, had taken SV since March 1977. Throughout the pregnancy her dosage was SV 1350 mg/day and phenytoin 450 mg/day divided in 3 doses.

In spite of therapeutic serum concentrations of these two drugs, she had had several major convulsions during early pregnancy. Delivery took place at term, the healthy boy (weight 3440 g, Apgar score 9/10) did not show any abnormalities; growth and development during the first year of life were normal as was the EEG.

Case 2

A 24-year-old woman, III para, who had suffered from epilepsy since 1968, was started on SV in January 1978 (4 months before conception). During pregnancy she was well controlled taking SV 1200 mg/day, phenytoin 400 mg/day, carbamazepine 600 mg/day, and clonazepam 1 mg/day. A healthy girl, weighing 4000 g was born at term. The Apgar score was 9/9, the initial EEG and development during the first 2 months were normal.

The serum level of SV was measured in the mothers at delivery and in the neonates at birth and repeatedly postnatally. At birth, SV levels were 220 and 110 µmol/l in the neonates, and 200 and 210 µmol/l in the mothers, but fell to insignificant concentrations by 5 days and were undetectable at 9 days (Figure).

The plasma concentration of glycine rose markedly during the first postnatal day, the highest levels being 665 and 605 µmol/l. These values differed very significantly from controls (Figure).

From these 2 case histories it is concluded that the use of SV in the last trimester of pregnancy induces a transient secondary hyperglycinaemia in the neonatal period, although the plasma glycine concentrations are clearly lower than in nonketotic hyperglycinaemia or organic acidaemia associated with hyperglycinaemia (Tanaka, 1975; von Wendt *et al.*, 1978). As these infants show normal psychomotor development, it is evident that this moderate rise of glycine concentration does not impair the development of the CNS. However, it should be borne in mind that treatment with SV during pregnancy can cause a false-positive finding in metabolic screening for aminoacidaemias in newborn babies.

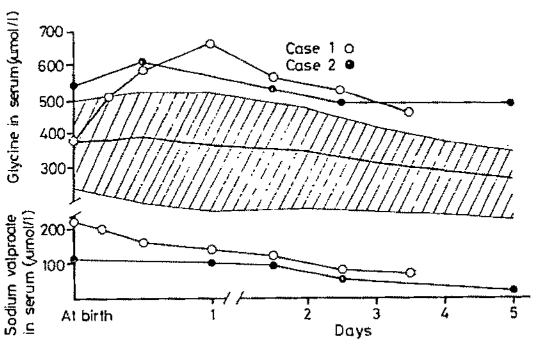

Figure *Glycine* (*upper part*) *and sodium valproate* (*lower part*) *in plasma and serum respectively in 2 newborn babies during the first 5 postnatal days. Normal range of postnatal glycine levels in plasma* (*mean* ± *SD, n* = *10*) *is shown by shaded area.*

Neutropenia during sodium valproate treatment

Sir,

Thrombocytopenia is a well-known side effect of sodium valproate (dipropylacetic acid) treatment (Winfield *et al.*, 1976; Raworth and Birchall, 1978; Sandler *et al.*, 1978). As far as we know, neutropenia has not been documented during valproate medication. Recently we treated a 3-month-old boy with sodium valproate (40 mg/kg per day) because of postanoxaemic convulsions. No other drugs were given. Total blood neutrophils decreased steadily from pretreatment values between 3·5 and 5·4 × 10^9/l to a value as low as 0·460 × 10^9/l during the next 2 months. Valproate was stopped and total neutrophil count promptly increased to 2·0 × 10^9/l within 14 days and to pretreatment values within a few weeks. Thrombocytes remained within normal limits. Erythrocyte count did not change. Because of the fragile condition of the infant a bone marrow puncture was not performed. Antibodies against thrombocytes have been shown in valproate-induced thrombocytopenia (Sandler *et al.*, 1978); in our patient immunofluorescence studies at the time of the lowest neutrophil count failed to demonstrate antibodies against granulocytes. Thrombocytopenia, and now neutropenia, as well as hyperglycinaemia (Jaeken *et al.*, 1977; Kamoun *et al.*, 1977), normal glycinorrhachia (Jaeken *et al.*, 1977), and ketonuria (Simon and Penry, 1975), all reported in association with sodium valproate medication, are classical findings in ketotic hyperglycinaemia (Scriver and Rosenberg, 1793). This suggests that sodium valproate can induce a biochemical syndrome similar to that of the ketotic hyperglycinaemias.

Book reviews

Clinical Pharmacology and Therapeutics: A Pediatric Perspective. Edited by Bernard L. Mirkin. (Pp. 339; illustrated + tables. £24.50 hardback.) YB Medical Publishers: Chicago. 1978.

After many teething difficulties, paediatric clinical pharmacology has come of age and a rapidly expanding data base resulting from excellent paediatric studies bears testimony to this fact. This book, based on a conference proceedings, and consisting of papers contributed by many of the foremost authorities on paediatric pharmacology, aims to identify the origins and nature of the available information, and to present it in such a way as to facilitate a rational approach to paediatric therapeutics.

It looks at five major areas of knowledge and concern. A discussion of factors modulating drug action in immature organisms provides an introduction to the second part which describes pharmacokinetic principles and their application to drug use, with particular reference to anticonvulsants and digoxin. The third section thoughtfully explores drug therapy in malignancy and virus diseases, and the more topical subjects of drug effects on lung maturation and the patent ductus arteriosus. Other problems of pre- and early postnatal drug therapy, the emotional disorders, and pharmacology of antihypertensive agents are clearly reviewed in the fourth part, and an excellent discussion on the general ethical principles governing drug research and investigation in children is included in the final section, which is mainly concerned with drug regulations more applicable to the USA.

The book, which makes no claim to being a comprehensive handbook of paediatric pharmacology, is a good one, and because of its nature, cannot be criticised for omissions. Its aims have been clearly achieved and there are no noticeable errors or unjustified statements. Readers looking for information on the treatment of specific paediatric problems will be disappointed, although they will not fail to recognise the principles on which a paediatric pharmacological approach is based and which are so firmly adhered to by the contributors. The paper on anticonvulsants by Morselli and Baruzzi particularly emphasises these principles by its numerous omissions of pharmacokinetic parameter values for almost half the drugs and age groups considered. Not for these authors the substitution of adult values for those of children, but rather an earnest plea for more data.

Paediatricians, who believe that the 'children are not small adults' maxim extends to drug use, will find much to interest them in this book.

GEORGE RYLANCE

Metabolic Disease in Childhood. By Leonard Sinclair. (Pp. 566; illustrated + tables. £27.50 hardback.) Blackwell: Oxford. 1979.

This book covers clinical, genetic, molecular, and therapeutic aspects of the great majority of metabolic disease in childhood. It is divided in three sections. The first deals with general topics—such as incidences, screening, genetic principles, and basic enzymology. The second section deals with symptomatology and common metabolic problems in paediatric practice. In the third and largest section, metabolic disorders are considered systematically and classified under the headings of disorders of active transport, disorders characterised by excessive storage or accumulation, disorders of intermediary metabolism, and disorders of synthesis. This logical classification of inborn errors of metabolism will help newcomers to the field in understanding the numerous and diverse consequences of disordered phenotypic expression of genetic enzyme defects. Further ramifications of the proposed reclassification are generally equally logical. However, the advantages of classifying Niemann-Pick disease and metachromatic leucodystrophy as examples of globosidosis (rather than of sphingolipidosis) are not evident, since the metabolic block in these disorders is in the removal of residues (phosphorylcholine, sulphate) which are not present in globoside. A number of slips (for example, induronidase, β-mamnosidase, Tay-Sachs gene in 1 in 1000 Ashkenazis) require correction in the next edition.

The easily readable, comprehe descriptions of these complicated often extremely rare disorders will b great value to clinicians, biochemists, others involved in the care of children v metabolic disorders.

P. F. BENS

Pediatric Cancer Chemotherapy. By R. A. Al-Rashid. (Pp. 319; illustrated + tables. £10.25 paperback.) Kimpton: London. 1979.

This soft-backed book provides a synopsis of the current state of the practice of paediatric cancer chemotherapy. The author, who is Director of the Pediatric Hematology and Oncology Service in the University of Nebraska College of Medicine, points out that because of continuing development in the field it is impossible to cover all aspects of drug therapy in malignant disease, and that treatment programmes for one tumour may vary from one centre to another. His aim is to provide a framework of information to enable clinicians in the field to understand the basis for the treatments. The first two chapters cover the clinical pharmacology of the anticancer drugs and the principles of cellular kinetics and chemotherapeutic strategy. The next 10 chapters cover the chemotherapy of the major paediatric malignancies, and the final one the late effects of cancer chemotherapy. The chapters dealing with specific disorders are subdivided into sections setting out the background development, discussion of different established regimens, and the treatment of recurrent disease.

This book suffers from the rather artificial division of chemotherapy from other modalities of management and could not be used to plan a whole treatment programme. In general, however, it provides an excellent reference to modern paediatric cancer chemotherapy in an easily readable and transportable form. It has an extensive bibliography, although references more recent than 1976 are rare.

Archives of Disease in Childhood, 1979, **54**, 1007–1019

Subject index Volume 54, 1979

Abdominal
  pain, acute, and viruses in childhood, **780**
    of nonorganic cause, recurrent, investigation using psychological tests, **165**, *P.*
Abortuses resulting from prenatal diagnostic surveillance for neural tube malformations, examination, **158**, *P.*
Achondrogenesis type II, histochemical and densitometric study of cartilage, **153**, *P.*
Adder bites in children: short report, **392**
Adenine phosphoribosyltransferase, complete deficiency presenting as renal stones, **25**
Adenovirus infection, type-21, pulmonary sequelae, 13-year follow-up, **155**, *P.*
Adrenal hyperplasia, salt-losing congenital, continuing need for mineralocorticoid therapy, **350**
Aldosterone and renin response in human newborns to acute blood volume change: correspondence, **80**
Allergy, bronchial, in cystic fibrosis, **164**, *P.*
Amino-acid metabolism and growth in infants with chronic renal failure, **321**, *P.*
Aminophylline IV and salbutamol IV, comparison in treatment of asthma: short report, **391**; correspondence, **983**
  intravenous, in apnoea, dosage schedule, **190**
Amniocentesis, diagnostic service, morbid anatomists' role, **152**, *P.*
Amniotic fluid, meconium-stained, increased concentrations of hypoxanthine and xanthine in, **727**, *P.*
Amyloid nephropathy in familial Mediterranean fever, **320**, *P.*
Anaemia in childhood coeliac disease: correspondence, **648**
Anal stenosis, congenital, delayed diagnosis: short report, **68**
Angiotensin and renin in normal prepubertal girls, **160**, *P.*
ANNOTATIONS
  A better deal for newborns with congenital heart disease, **268**
  Diagnosis of malignant hyperphenylalaninaemia, **329**
  Genetic registers, **169**
  Red cell aplasia in children, **263**
Antidiuretic hormone secretion, inappropriate, in mechanically-ventilated newborn infants, **320**, *P.*
Antigen-antibody complexes in serum in juvenile chronic arthritis, **120**
Antipyrine
  drug metabolism in malnourished children, **299**
  treatment, maternal, in neonatal jaundice prophylaxis, **725**, *P.*
Aortic arch interruption presenting with absence of all limb pulses, **49**
Aortography in infantile coarctation: short report, **717**
Apnoea
  alarm systems, explanation for failure, **982**, *P.*
  and hypoventilation in neonate, use of doxapram, **981**, *P.*
  intravenous aminophylline in, dosage schedule, **190**
  of prematurity, relation to differential delay in myelination of vagal fibres, **153**, *P.*
  theophylline half life: short report, **238**
Arrhythmias, cardiac, and prolonged QT interval in two neonates, sudden infant death syndrome in one, **776**
Arterial oxygen tension
  continuous measurement, improved accuracy, sick newborn infant: short report, **307**
  servo-control, new technique, preterm infants, **278**
Arteriosonde, Infrasonde, and mercury sphygmomanometer, clinical evaluation and comparison, **184**; **160**, *P.*; erratum, **420**
Arteritis, Takayasu's, as differential diagnosis from systemic juvenile chronic arthritis: short report, **798**
Arthritis, juvenile, chronic,
  antigen-antibody complexes in serum, **120**
  systemic, Takayasu's arteritis as differential diagnosis: short report, **798**
Aspergillosis, neonatal, accompanying fulminant necrotising enterocolitis: short report, **559**
Aspirin, rectal, absorption and antipyretic effect: short report, **713**
Asplenia in the Ivemark syndrome, evidence against primary agenesis, **153**, *P.*
  polysplenia, comparative study of susceptibility to infection, **153**, *P.*
Asthma childhood,
  acute, use of nebulised salbutamol, **163**, *P.*
  bronchial, in Nigerian children, **448**
  controlled trial of family psychotherapy, **116**
  comparison of salbutamol IV and aminophylline IV: short report, **391**
  house dust mite sensitive, hyposensitisation in, **164**, *P.*
  use of nebulised chlorpheniramine, bronchodilator effects, **163**, *P.*
  effects of physical training on hormonal responses to exercise, **524**
AT10 (dihydrothachysterol) in treatment of hypercalcaemia: correspondence, **82**
Ataxia-telangiectasia, diagnostic considerations, **682**
Azathioprine and cyclophosphamide, controlled trial in nephrotic syndrome and poorly selective proteinuria, **204**

Bacteria, role in acute wheezy bronchitis, **587**
Basal acid secretion, serum cholecystokinin and infantile pyloric secretion, **773**
Beclomethasone dipropionate, clinical comparison of aerosol, or as powder from rotohaler: short report, **233**
Behaviour
  deviance after early treated phenylketonuria, **14**
  disturbance, in 3-year-olds, followed up study, **970** *P.*

Betamethasone, follow-up study of babies exposed to before birth, **725**, *P.*
Betamimetics and neonatal lung adaptation, **153**, *P.*
Bile,
  acids, concentrations, total serum, postprandial, in cystic fibrosis, **164**, *P.*
    duodenal, in protracted diarrhoea, infants, **131**
  salts, intestinal, in cystic fibrosis, **19**
Bites, snake, in children: short report, **392**
Bleeding, vaginal, recurrent, in infants and young girls without other evidence of precocious puberty: short report, **472**
Blood,
  formation in infancy: annotation, **831**
  pressure in first six weeks of life, **726**, *P.*
    measurement, comparison and clinical evaluation of Infrasonde, Arteriosonde, and mercury sphygmomanometer, **184**: **160**, *P.*: erratum, **420**
  Rh type, maternal, and spina bifida: correspondence, **567**
  transfusion, and cytomegalovirus in neonates, **538**
  volume change, renin and aldosterone response in human newborns: correspondence, **80**
Body,
  fat in newborn: annotation, **845**
  fatness, height and weight, family resemblance, **877**
  see also Fat
Bone,
  growth and mineralisation, effect of puberty on rates, **950**
  marrow relapse on treatment in childhood acute lymphoblastic leukaemia, **974**, *P.*
Bowel,
  disease, inflammatory, acute in childhood: a new disease? correspondence, **906**
  small, biopsy, critical assessment, **604**
    neonatal small left colon syndrome: short report, **635**
Breast
  development in the neonate, **979**, *P.*
  feeding and smoking: correspondence, **240**
  milk, bacteriological criteria for feeding to babies on SCBU, **804**, *P.*
    and breast feeding in very low birthweight infants: short report, **897**
    caffeine secretion: short report, **787**
    cell concentrations, after storage, in glass and plastic containers, **981**, *P*
    unheated, bacteriological monitoring, **760**
Breath hydrogen test for detecting lactose malabsorption, **436**
Breech delivery and hypopituitary dwarfism: correspondence, **485**
Bronchial allergy in cystic fibrosis, **164**, *P.*
Bronchial asthma, in Nigerian children, **448**
Bronchitis, acute wheezy, role of viruses and bacteria, sputum study, **587**
Bronchodilator,
  drugs and young children: correspondence, **649**
  effects of nebulised chlorpheniramine in childhood asthma, **163**, *P.*
Buccal epithelial cells, *E. coli* adhesion, **162**, *P.*
C-reactive protein test in diagnosis of septic complications of CSF shunts for hydrocephalus, **545**
Caffeine,
  elimination, maturation in infancy, **946**
  secretion into breast milk: short report, **787**
Calcification, arterial, diffuse, and hydrops fetalis, **154**, *P.*
Calcium, ionised, in pregnancy, **980**, *P.*
Calculi, bilateral staghorn cystine renal, dissolution: short report, **795**
Candida, defective killing in childhood malnutrition, **445**
Candidiasis,
  mucocutaneous, complicating neonatal intensive care, **158**, *P.*
  pulmonary, in cystic fibrosis: short report, **555**
  systemic, presenting feature in acute anuric renal failure: short report, **70**
Carbamazepine dose-frequency requirement in children, **454**
Carbohydrate metabolism in chronic renal failure, **321**, *P.*
Cardiac,
  action during haemodialysis, echocardiographic investigation, **322**, *P.*
  malformations, congenital, *see* Heart disease, congenital
Cardiovascular diseases, risk factors in children, **320**, *P.*
Caries, dental,
  and addition of sugar to liquid medicines, **974**, *P.*
  incidence in coeliac disease: correspondence, **166**, **566**
Cartilage, histochemical and densitometric study in achondrogenesis type II, **153**, *P.*
Catheterisation, umbilical, securing haemostasis during, neonate: correspondence, **166**
Catheters, umbilical, simple method for stabilising: correspondence, **563**
Cefuroxime plasma and CSF levels in meningitis: short report, **235**; correspondence **729**
Cells, buccal epithelial, *E. coli* adhesion, **162**, *P.*
Cerebral lesions, ischaemic, and congenital cardiac malformations, **156**, *P.*
Cerebrospinal fluid immunoglobulins in children: short report, **961**
Cervical lymphadenitis due to mycobacteria of the Fortuitum group: short report, **312**
Chickenpox, Henoch-Schönlein purpura after: correspondence, **166**, **564**
Chloramphenicol and phenobarbitone—drug interaction: short report, **76**: correspondence, **563**
Chlorhexidine, absorption from the intact skin, newborn infants, **379**
Chlorpheniramine, nebulised, in asthma, bronchodilator effects, **163**, *P.*
Chromosome,
  abnormalities, and immunodeficiency, four families with, **518**
  3 (3q), long arm, familial partial trisomy, **135**
  ring 20, with seizures, minor anomalies, and retardation: short report, **477**
Cholecystokinin, serum, basal acid secretion, and infantile pyloric stenosis, **773**
Chorioamnionitis and funisitis due to *Corynebacterium kutscheri*, **710**

Ciliary anomalies, congenital, and respiratory disease, **159,** *P.*
Circulatory arrest with profound hypothermia in infancy, intellectual performance after, **1**
Cirrhosis, liver,
  modification by colchicine of hepatic collagen synthesis, **160,** *P.*
  Indian childhood, raised hepatic copper concentration in, **803,** *P.*
  and hepatitis A: short report, **901**
Clinic form, child-health, suggested design: current topics, **626**
Clomipramine therapy, maternal, neonatal effects: correspondence, **405**
Clonidine, dose in alternating hemiplegia: correspondence, **327**
Clubbing, digital, quantitation by shadowgram technique: short report, **145**
Coarctation, infantile, aortography: short report, **717**
Coeliac disease,
  childhood, and anaemia: correspondence, **648**
  dental caries, incidence: correspondence, **166, 566**
  diagnosis, Interlaken criteria: current topics, **783**
  on gluten-free diets, small bowel mucosal changes in asymptomatic children with, **803,** *P.*
  in identical twins at same age in both: short report, **395**
  iron deficiency on gluten-free diet, **375**
Colchicine, in modification of hepatic collagen synthesis in cirrhosis of liver, **160,** *P.*
Colitis, granular-cystic, persistent or chronic diarrhoea, pathological changes, **157,** *P.*
Colon, small, left, neonatal, syndrome: short report, **635**
  see also Bowel
Compensatory hypertrophy of renal size in chronic pyelonephritis and unilateral renal damage, **320,** *P.*
Complement,
  activating factor in membranoproliferative glomerulonephritis, **323,** *P.*
  deficiency with membranoproliferative glomerulonephritis, recurrence after transplant, **323,** *P.*
  profiles in glomerulonephritis, acute or membranoproliferative, **323,** *P.*
  system, abnormalities with liver disease, **160,** *P.*
Congenital
  dislocation of the hip, pathology, **152,** *P.*
  fibre type disproportion myopathy, histological diagnosis with an uncertain clinical outlook, **735**
  heart disease, a better deal for newborns; annotation, **268**
Connective tissue disorders, maternal, associated with congenital complete heart block in newborn, **7; 727,** *P.*
Consanguinity, parental, and fetal growth: short report, **317**
Continuous positive airways pressure, discontinuation in infants with respiratory distress syndrome: short report, **722**
Convulsions,
  diazepam, rectal administration, in acute treatment, **855**
  febrile, associated with hydroxykynurenine hydroxyanthranilic acid ratios, **801,** *P.*
  prophylactic diazepam in: correspondence, **244**
  role of viruses, **869**
  see also Seizures
Copper,
  concentration, hepatic, raised, in Indian childhood cirrhosis, **803,** *P.*
  deficiency in a low birthweight infant: short report, **553**
Cord blood screening, regional, results of programme for detecting neonatal hypothyroidism, **171**
Coronary arterial lesions, and myocardial necrosis in stillbirths and infants, **918**
CORRESPONDENCE

PEDIATRIC RESEARCH

Volume 13, No. 9 September 1979

Contents

The Zinc, Copper, Manganese, Vanadium, and Iodine Content of Hair from 38 Canadian Neonates 000

R. S. Gibson and M. S. DeWolfe (Halifax, Nova Scotia, Canada)

This investigation was undertaken to establish "normal values" for the zinc, copper, manganese, vanadium, and iodine concentrations of hair in 38 full-term neonates.

Parathyroid Hormone Response in Newborn Infants during Exchange Transfusion with Blood Supplemented with Citrate and Phosphate: Effect of iv Calcium 111

P. Wieland, G. Duc, J. A. Fischer, and U. Binswanger (Zurich, Switzerland)

The authors attempt to investigate parathyroid secretory function in newborn infants before, during, and after exchange transfusion and to assess whether iv calcium supplementation can prevent the decrease in serum ionized calcium as well as the prolongation of Q–oTc intervals during exchange transfusion with donor blood preserved in citrate and phosphate

Protease Inhibitors in Human Milk 222

T. Lindberg (Malmo, Sweden)

This investigation reports the occurrence, electrophoretic properties, and amounts of some protease inhibitors in human milk from birth to 4 months after delivery.

Serum Concentration of 24, 25-Dihydroxyvitamin D in Normal Children and in Children with Rickets 333

T. M. Nguyen, H. Guillozo, M. Garabedian, E. Mallet, and S. Balsan (Paris, France)

This paper describes the method of 24, 25-(OH)$_2$D measurement in serum and reports the results obtained in normal children as compared with normal adults, in children with Vitamin D deficiency or Vitamin D-resistant rickets, and in one child intoxicated with ergocalciferol.

Ketotic Episodes in Glutaryl-CoA Dehydrogenase Deficiency (Glutaric Aciduria) 444

N. Gregersen and N. J. Brandt (Aarhus and Copenhagen, Denmark)

The finding of metabolites derived from the catabolism of branched-chain amino acids and the fatty acid in urine samples from a patient with glutaryl-CoA dehydrogenase deficiency indicate an inhibition of acyl-CoA dehydrogenases in the patient.

The Effect of Sleep State on Chest Distortion and on the Ventilatory Response to CO$_2$ in Neonates 555

M. Davi, K. Sankaran, M. MacCallum, D. Cates, and H. Rigatto (Winnipeg, Manitoba, Canada)

The prevalence of chest distortion and the ventilatory response to CO$_2$ was measured during non-REM and REM sleep in neonates.

Effect of Cigarette Smoke Exposure on Maturation of the Antibody Response in Spleens of Newborn Mice 666

H. B. Herscowitz and R. B. Cooper (Washington, D. C.)

These results indicate that the maturation of the splenic antibody forming cell response in developing mice was significantly inhibiting as a consequence of exposure to cigarette smoke.

The effect of Diazepam Upon the Development of Hypertension in the Spontaneously Hypertensive Rat 777

R. M. Schieken (Iowa City, Iowa)

This study describes the long-term antihypertensive effects of the chronic administration of diazepam to young spontaneously hypertensive rats (SHR).

Effect of Hydrocortisone on the Metabolism of Phosphatidylcholine in Maternal and Fetal Rabbit Lungs and Livers 888

F. H. C. Tsao, G. R. Gutcher and R. D. Zachman (Madison, Wisconsin)

This investigation was undertaken to examine the effects of antenatal maternal steroids on phosphatidylcholine (PC) metabolism in maternal lung and liver in comparison with effects on fetal PC metabolism.

A Study of Inheritance in Progressive Intrahepatic Cholestasis: Hepatic Excretory Function in Unaffected Family Members 999

P. Bidot, D. R. LaBrecque, Y. E. Hsia, and C. C. A. Riely (New Haven, Connecticut)

In an attempt to identify the heterozygous state for PIC hepatic excretory function was studied in the parents and four second degree relatives of two brothers with PIC.
